# APPLIED SURGICAL ANATOMY

REGIONALLY PRESENTED

FOR THE USE OF STUDENTS AND PRACTITIONERS  
OF MEDICINE

BY

GEORGE WOOLSEY, A. B., M. D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE.  
SURGEON TO BELLEVUE HOSPITAL, ASSOCIATE SURGEON TO THE PRESBYTERIAN  
HOSPITAL, FELLOW OF THE AMERICAN SURGICAL ASSOCIATION  
AND OF THE NEW YORK ACADEMY OF MEDICINE

WITH 125 ILLUSTRATIONS, MOSTLY COLORED

LEA BROTHERS & CO.  
NEW YORK AND PHILADELPHIA,

1902

Entered according to the Act of Congress in the year 1902, by

## PREFACE.

THE study of Anatomy is relieved of much of its difficulty when it is approached on the practical side. Isolated details do not appeal to the faculty of interest, but when they are set forth in their natural relationship, and their practical application is pointed out, the mind grasps and recollects them with facility. As Anatomy is the most basic of all the medical sciences, a working knowledge of its data is indispensable for the study and practice of scientific medicine and surgery. The author has endeavored to embody these principles in the present work, and to do it in such a manner as to answer the needs of both students and practitioners.

The plan of the work has been developed from twelve years' experience in teaching Anatomy. The author believes the form of presentation he has followed to be the best for didactic lectures, and that descriptive Anatomy is most advantageously learned from textbooks and in the dissecting room. The regional and topographical method of treating Applied Anatomy is likewise the most convenient for clinical purposes.

It is scarcely necessary to state that in order not to exceed the proper limits of a book designed for clinical and didactic purposes a most careful selection had to be made from the vast aggregate of knowledge constituting the modern science of anatomy. If in parts the text may appear quite as much like an anatomical surgery as a surgical anatomy, it is because of the author's belief that this is the best way to complete the study of anatomy and to begin the study of surgery.

The author desires to acknowledge his indebtedness to the excellent words of Joessel, Tillaux, Merkel and others, both for anatomical facts, the methods of their presentation, and for numerous illustrations. An original work on such a subject can no longer be written, nor would it have as much value as a volume duly recognizing the vast fund of information accumulated by tireless investigators. A single author can only hope to contribute a fair proportion of original knowledge and to present a chosen aspect of the science in a clear and practical manner.

# APPLIED SURGICAL ANATOMY.

---

## CHAPTER I.

### THE HEAD AND NECK.

#### THE HEAD.

**General Considerations.**—The head is anatomically the most essential and most complex part of the body. It is of great practical interest, for even its smaller parts are of importance to the life and well-being of man. In individuals of medium height and weight the head measures  $\frac{1}{8}$  of the body height in men and  $\frac{7}{5}$  in women, and weighs  $\frac{1}{17}$  of the body weight in men (4 k.g.) and  $\frac{1}{16}$  in women (3.6 k.g.). The larger the individual so much smaller is the head as compared with the total height and weight.

When the face looks directly forward the external auditory meatus and infraorbital margin are in a horizontal plane. Such a position, the one most naturally assumed, is maintained by the posterior neck muscles and not by gravity, for the line of the latter lies in front of the transverse occipito-atlantoid axis of motion.

As compared with the human skull that of the *higher apes* (chimpanzee, orang, etc.) shows marked differences, *i. e.*, the projection of the muzzle, the greater size and forward position of the face, the greater size of the intermaxillary bones, the backward and oblique position of the foramen magnum, etc. *Idiots' skulls* approximate those of the lower animals in many respects, *i. e.*, large face, small cranium, etc.

The head shows a tendency to *asymmetry*. One error often compensates for another and one is often astonished in the examination of the separate parts to find considerable deformity whose existence escapes a general observation. Individual differences in the head are marked, as they are elsewhere in the body, but we are accustomed to observe them more closely as they are the essential marks of individuality.

But besides the individual differences there are those of sex, age and race. Thus the female skull looks immature, resembling that of a child, and is smaller, lighter, broader and less high, the face and lower jaw are smaller and the vertex is flattened. The circumference of the skull at birth is greater than that of any other part of the body. The skull at birth is characterized by the large size of the cranium and the small size of the face and the base; the absence of

the mastoid process, the diploë and all ridges; the presence of the anterior fontanelle and the prominence of the frontal and parietal eminences. It resembles more closely the skull of the lower animals than does the adult skull.

During the *first seven years* the skull grows very rapidly, at first more or less equally. During the first dentition the fontanelles close, the face broadens and enlarges, the jaws lengthen and the zygomatic arches project. Later the base of the skull lengthens and the face becomes deeper and somewhat longer. By the seventh year some parts have attained their growth, *i. e.*, the foramen magnum, the petrous portion of the temporal bone, the width of the body of the sphenoid and of the cribriform plate. Near the approach of *puberty* a second period of active growth begins, the face is elongated from the increased height of the nasal fossæ, alveolar arches and second teeth and the expansion of the air sinuses. In *later years* the latter continue to expand, up to old age, the crests and ridges develop and the frontal region elongates. In *old age* the skull atrophies, becoming thinner, lighter and perhaps smaller by absorption on the surface and redeposit on the interior. The face becomes smaller by the loss of the teeth and the absorption of the alveolar processes.

The racial differences although marked in typical examples shade into each other. According to one classification we may distinguish: (1) the *prognathous* or long-headed type, with projecting jaws and teeth, as in the negro, (2) the *pyramidal* or broad, flat-faced type, with narrow forehead, as in the Mongolian or Esquimaux and (3) the *oval* type of the European, with the length of (1), or even more, and the breadth of (2), but the teeth do not project as in (1) nor the zygomatic arches as in (2), and the forehead is full, laterally, and high. Again skulls are classified as I. *Dolicocephalic*, or "long-headed," in which the occipital lobes overlap the cerebellum and II. *Brachycephalic*, or "short-headed," in which the occipital lobes do not extend so far backward. Each division is subdivided into *orthognathous* in which the jaws and teeth do not project and *prognathous* in which they do.

Other peculiar forms of skull are on the border line of pathological deformities, depending upon the premature closure of a certain suture which prevents the growth of the skull at right angles to that suture and forces it to grow in other directions, if at all. By the same process, extended to several sutures, microcephalus may result. The latter may be the result or cause of idiocy, in the latter case justifying operation (craniectomy).

### THE SCALP.

The soft parts covering the vault of the skull are arranged as in no other part of the body. There are five layers: (1) The skin, (2) the subcutaneous fatty tissue, (3) the occipito-frontalis muscles and aponeurosis, (4) the subaponeurotic areolar tissue, and (5) the peri-cranium. The *first three layers* are so intimately blended with one

another, especially over the aponeurotic portion of the occipito-frontalis, that they form virtually a single layer, the scalp (see Fig. 1).

FIG. 1.

Frontal section of scalp and skull through the sagittal suture and the superior longitudinal sinus.

**1. The skin** of the scalp is thicker than that in most regions of the body and is thicker behind than in front. The hair is so strongly attached to the scalp that it has supported the weight of the body in many instances since the days of Absalom, as for example where it is caught in revolving machinery belts and the body is drawn after it. The entire scalp has also been torn off in such accidents. The hair should always be shaved around scalp wounds, otherwise it is impossible to make and keep them clean. Although the roots of the hairs may extend deeply into the subcutaneous fatty tissue the numerous *sebaceous glands* associated with them are superficial in the skin. These may develop into **sebaceous tumors** or wens which are more common here than in any other part of the body. Owing to their superficial position, external to the aponeurosis, they are easily and safely removed. Care must be taken however in removing suppurating sebaceous cysts not to divide the aponeurotic layer on account of the danger of infection of the loose tissue beneath.

**2. The subcutaneous tissue**, 5–6 mm. in thickness, is composed of a great number of strong fibrous bands closely binding together the skin and aponeurosis and forming a multitude of small compartments enclosing lobules of fat. On account of this disposition of the fat it follows that fatty tumors are rare and that there is but little increase of it in obesity, though a perceptible decrease exists after long sickness. The falling out of the hair in such cases may be partly due to this fact.

The arrangement of this subcutaneous tissue, like that in the palm, admirably adapts it to resist pressure. It makes the density of the scalp such that in surface inflammations, as in erysipelas, the scalp

swells but slightly, is but little reddened and is extremely painful. It attaches the skin so closely to the aponeurosis and muscle that the former moves with all the movements of the latter. Furthermore this layer contains the vessels which supply the three layers of the scalp. These vessels are closely connected with the fibrous partitions of this layer so that in wounds of the scalp the vessels which are divided are unable to retract or contract, hence hemorrhage is free and is not spontaneously arrested. *Tumors* situated external to the aponeurosis move with the scalp; immovable growths are probably beneath the aponeurosis.

3. **The aponeurosis** occupies the space between the two muscular portions of the occipito-frontalis, in front and behind. It extends down laterally over the temporal fascia as a cellular layer, and over the zygomatic arch without attachment to it.

4. **The subaponeurotic areolar layer** is a layer of loose connective tissue whose looseness serves, like a serous membrane, to facilitate the movement of the scalp upon the pericranium, a condition which is more marked in the young than in the old. This looseness of attachment allows the gaping of scalp wounds and the ready separation of large flaps of scalp by injuries, operations, scalping by Indians or in autopsies. It is known as the **dangerous area** of the scalp, for its loose structure allows the wide and rapid spread of inflammation and pus, posteriorly as far as the superior curved line, anteriorly to the superciliary ridges, and laterally to or even below the level of the zygoma. Wounds or incisions which extend through the entire scalp and open into this layer are much more serious than more superficial ones on account of the more serious consequences of infection. This layer contains but few blood vessels which cross it to enter the pericranium, otherwise large effusions of blood would be far more common here than they are.

5. **The pericranium** is remarkable for its slight adherence to the bone except along the sutures, where it is attached to the suture membrane and is thus continuous with the dura, as it is also at the foramina. Hence inflammation of the pericranium may extend by continuity to the dura at the foramina and sutures where the two become continuous. It follows also that the pericranium may be widely stripped up from the underlying bone in extensive scalp wounds. Such an injury is of less importance than we would expect from analogy with similar injuries of the periosteum elsewhere. The skull bones seldom necrose under such circumstances, for they derive their main blood supply from the vessels of the diploë and dura. For a similar reason loss of bone in the vault of the adult skull due to injury, necrosis or operation, is as a rule not repaired, for neither the pericranium nor the dura reproduce bone as does the periosteum.

**Vessels of the Scalp.**—The vascularity of the scalp is greater than that of any other part of the surface. Flaps of scalp, however large and extensively stripped up, almost always live, for the scalp carries its own blood supply, which enters at the pedicle of the flap. Slough-

ing and gangrene from pressure are rare owing to the density of the scalp tissue in which the vessels run. Unlike other regions of the body, where vessels of any size are subfascial, the vessels of the scalp lie in the subcutaneous tissue alone.

The arteries come from the occipital, posterior auricular and superficial temporal branches of the external carotid and from the supraorbital and frontal branches of the ophthalmic. Each vessel converges upward toward the vertex of the skull and anastomoses freely with the adjoining ones and with its fellow of the opposite side. It follows that *incisions* should be planned as far as possible to radiate from the vertex, or, if horseshoe-shaped, to have the base below and the free end toward the vertex. To prevent hemorrhage during an operation rubber tubing may be tightly drawn around the base of the scalp, or to diminish it overlapping, interrupted, temporary sutures may be applied between the incision or flap and the base of the scalp, from whence the arteries pass upward. The *frontal artery* emerging at the inner angle of the orbit on each side, enters at the base of and supplies the flap that is taken from the forehead to form a new nose in rhinoplasty. The *temporal artery* with the auriculo-temporal nerve behind it ascends between the condyle of the jaw and the external auditory meatus over the posterior root of the zygoma and divides into its anterior and posterior branches 1½ to 2 inches above the latter. It presents in a high degree the tortuosities of the arteries of the head, especially its anterior branch, and, in the aged, it affords early evidence of arterial sclerosis. It is the most frequent situation for cirroid aneurism and is more frequently wounded than almost any other artery of the body. The *posterior auricular artery* and nerve run in the angle between the ear and the mastoid process. The *occipital artery* ascends a finger's breadth behind the mastoid process and reaches the scalp, with the great occipital nerve a little internal to a point midway between the mastoid process and the occipital protuberance. These arteries all share the peculiarity of being subcutaneous instead of being subaponeurotic.

The **emissary veins** connect the dural sinuses with the superficial veins at certain points through apertures in the skull and hence are of considerable practical importance. They afford a channel for the spread of inflammation from the surface, to the sinuses or meninges, thereby causing sinus thrombosis or meningitis, as in cases of erysipelas and suppuration of the scalp or necrosis of the cranial bones. Their presence adds greatly to the seriousness of injuries and diseases of the scalp. They also assist in equalizing the intracranial pressure and for this purpose are most developed in early life, during the period of brain growth.

The most constant and important of the emissary veins connecting with the veins of the scalp are: (1) the vein passing through the mastoid foramen which connects the lateral sinus with the occipital (or posterior auricular) vein; (2) the vein passing through the posterior condylar foramen which connects the sigmoid sinus with the deep

veins at the back of the neck ; (3) the vein passing through the parietal foramen which connects the superior longitudinal sinus with the veins of the scalp. The *mastoid emissary vein* accounts for the practice of blood letting or blistering behind the ear in some cerebral affections and for the oedema behind the mastoid process in lateral sinus thrombosis. For the other emissary veins see any descriptive anatomy.

The veins of the scalp are also connected by many minute veins with the *veins of the diploë*. The latter are not well developed until after the tenth year when the diploë develops and they are separate for each bone until the ossification of the sutures (Testut). The veins of the diploë communicate, the anterior two (frontal and anterior temporal) with the surface veins (supraorbital and deep temporal), the posterior two (posterior temporal and occipital) with the lateral sinus. The anastomosis between the angular and supraorbital veins at the inner angle of the orbit affords a free communication between the extra- and intracranial circulation, as the supraorbital vein through the ophthalmic is a tributary of the cavernous sinus. Thus we see the number of channels, and there are other less conspicuous ones, through which inflammation can spread from the surface to the interior of the skull.

**The lymphatics** of the scalp may be divided into three groups : (1) The occipital emptying into the suboccipital nodes ; (2) the posterior parietal emptying into the mastoid nodes, and (3) the anterior parietal and frontal which empty into the parotid nodes. Some vessels from the frontal region end in the submaxillary nodes. A knowledge of these regions and their nodes is of service in the diagnosis of scalp troubles in which they are affected.

With regard to the **nerves** which supply the scalp it is only necessary to say that those which are branches of the fifth nerve are not infrequently the seat of neuralgia, especially the *supraorbital nerve*, less often the auriculo-temporal. The former emerges from the orbit at the supraorbital foramen or notch, at the junction of the inner and middle thirds of the supraorbital margin. Here it may be readily found and divided or resected in some forms of obstinate frontal headache due to neuralgia of this nerve. The inner branch reaches back to the middle of the parietal bone, the outer branch as far as the lambdoid suture.

**Wounds** of the scalp do not gape unless the aponeurosis or muscle is divided. Those wounds gape most which are transverse to the muscle fibers, next those transverse to the aponeurotic fibers, and those gape least which are parallel with them, *i. e.*, antero-posterior. As the scalp is firmly stretched over the hard bone beneath, contused wounds often appear as cleanly cut as incised wounds. Wounds resembling incised wounds may also be produced from within by the sharp edge of the superciliary ridge when struck by a blunt object.

**Bleeding** from scalp wounds is very free and unless properly treated very prolonged. There is little or no tendency to the spontaneous arrest of hemorrhage, for the arteries, owing to their adhesion to the tissues of the scalp, are unable to retract or contract when divided,

and it is by this process that bleeding is ordinarily spontaneously arrested. This adhesion and the density of the scalp account for the difficulty of tying a bleeding artery in the scalp, hence to arrest hemorrhage we often depend upon pressure, a suture passed beneath the vessel or upon suturing the edges of the wound firmly together. Fortunately, as we have seen above, there is very little danger of sloughing on account of pressure. In addition to the arrest of bleeding we have to think of the possibilities of inflammation in scalp wounds.

**Inflammation or abscess** in the scalp may occur in one of three situations, (1) in the subcutaneous tissue, (2) between the aponeurosis and the pericranium, and (3) beneath the pericranium. Abscesses of the first variety are small and spread only with the greatest difficulty in the dense tissue. In the second situation inflammation or abscess may be very serious on account of its easy spread in the loose tissue and the danger of the infection extending within the cranium. Inflammations of this kind may follow scalp wounds involving the aponeurosis and the chief danger of these wounds lies in such inflammations. The inflammation may undermine the entire scalp and is limited only by the attachments of the aponeurosis as given above. The scalp does not perish even in the most extensive cases, as it carries its own blood supply, but the wounds which lead to the abscess or are made to relieve it are often slow to heal, as the abscess walls fail to obtain perfect rest owing to the movements of the occipito-frontalis muscle. Abscess beneath the pericranium is limited to the surface of one bone as this membrane is adherent to the suture membrane. It is most often the result of necrosis of the cranial bones.

**Hæmatomata** of the scalp may be classified in the same manner as abscess. They occur most frequently outside of the aponeurosis in the subcutaneous tissue which contains the greater part of the blood vessels. In this situation the extravasation of blood is usually small and sharply limited by the density of the tissues and is confined to the area where the tissues are lacerated by violence. Such extravasations of blood produce a tumor on the surface whose thin edges become hard from the coagulation of the thin layer of blood while the thicker center remains soft for a time. A firm sharp margin often separates these two parts which may lead to a mistake in diagnosis by mistaking it for the margin of a fracture of the skull and the soft center for the depression of an area of the skull. This error may be avoided by observing the projection of the blood tumor on the surface and by moving the scalp back and forth, when the supposed depressed area moves with the scalp over the surface of the skull. Owing to its poverty in blood vessels the loose tissue beneath the aponeurosis is not often the seat of a hæmatoma except as the result of fracture of the skull. When they occur here they may attain a large size and may similarly present hard edges and a soft center, simulating depressed fracture, from which they cannot be distinguished by moving the scalp.

Extravasations of blood beneath the pericranium are limited in area to one bone and may be diagnosed by this fact. They are commonly

called *cephalhematomata*, are usually congenital in origin, due to pressure on the head at birth, and hence are more frequent in males owing to the larger size of the head. They are most common over the parietal bone and on the right side, which is most exposed to pressure. Besides these blood tumors beneath the pericranium others occur rarely which have a different origin and are distinguished by disappearing on pressure, in whole or in part, or even in the upright posture. Such tumors according to their position are connected either with the veins of the diploë or the dural sinuses through an opening which may be the result of injury, disease or congenital defect. When communicating with the superior longitudinal sinus they are median and receive a faint pulsation from the brain.

### THE TEMPORAL REGION.

The temporal region varies in some respects from the scalp proper as to the soft parts covering it. The limits of this region may be taken to be the upper border of the zygomatic arch, the external auditory meatus and the base of the mastoid process below and the curved superior temporal ridge above. The latter ridge connects the base of the mastoid bone with the external angular process of the frontal bone and rises 7 to 8 cm. above the level of the zygomatic arch. This region corresponds to the temporal fossa and its upper limits may be determined by making the temporal muscle to contract. The various layers of soft parts common to this region and the occipito-frontal are identical above, where they really form a part of the scalp, but change in character below. Thus the skin, below, is less dense, less thick and less adherent to the subcutaneous tissue and is wanting in hair below and in front. The subcutaneous tissue, below, becomes loose and resembles that elsewhere in the body and the arteries are no longer intimately adherent to its septa. The aponeurosis passes down over the zygoma onto the cheek, becoming loose, thin and lamellar. The loose subaponeurotic tissue is like that above, but loosely connects the aponeurosis with the temporal fascia instead of with the pericranium.

The **temporal fascia**, whose form represents exactly that of this region, is very dense and unyielding, so that in the case of an injury reported by Denonvilliers a lacerated wound of this fascia was at first mistaken for a fracture of the skull. In its lower third it is double, enclosing fat and the orbital branch of the temporal artery between its two layers, which are attached to the outer and inner aspects of the upper border of the zygomatic arch. Between it and the bone is an osseo-aponeurotic space which is deepest in front ( $2\frac{1}{2}$  cm.) and narrows behind and above until we reach the attachment of the fascia to the bone. This space lodges the temporal muscle and deep temporal vessels and nerves. It is hermetically closed above by the attachment of the fascia to the temporal ridge, while below it is directly continuous with the zygomatic fossa, so that surgically the two fossæ form but a single region. Hence abscess, etc., in the temporal fossa is prevented

by the firm fascia from opening above the zygoma and tends to extend downward into the zygomatic fossa and the neck. Owing to the density of the fascia pathological collections beneath it do not show on the surface.

As in the scalp, inflammatory products or blood may collect in the subcutaneous or subaponeurotic layers, in which situations they may be wholly above the zygoma or sink in part below its level. Subcutaneous effusions lie external to the zygomatic arch while those beneath the fascia are internal to the arch. In the temporal region the pericranium is much thinner and more adherent to the bone while the dura is less so than it is above, hence subpericranial extravasations are rare while epidural extravasations are more common than elsewhere.

As the muscle is separated from the fascia in the lower third of this region by a mass of fat, continuous with the abundant masses in the zygomatic fossa, we see that there are three distinct layers of fat between the surface and the muscle: (1) Subcutaneous, (2) interfascial, (3) subfascial. This fat diminishes in wasting diseases, giving a sunken appearance to the temporal region, and bringing the zygomatic arch and the malar bone, below and in front, into prominent relief.

The **mastoid region**, corresponding to the triangular mastoid process, is covered by the same layers as the occipito-frontal but the skin, subcutaneous, aponeurotic and subaponeurotic tissues are altered as in the lower temporal regions so as to resemble the similar layers elsewhere in the body. The pericranium is very thick and adherent and is more like periosteum elsewhere.

## THE BONY CRANIUM.

**Surface Landmarks.**—Those that can be determined through the overlying scalp are of the most surgical importance in relation to crano-cerebral topography. The **external occipital protuberance**, or **inion**, is readily felt in the median line. It is the thickest part of the vault and corresponds about to the torcular Herophili on the inner surface. The **gabella**, the median smooth area between the superciliary ridges of the frontal bone, can be felt just above the notch (*nasion*) at the naso-frontal suture. The **external angular process** of the frontal bone at the outer end of the supraorbital ridge is readily felt. Measurements are taken from its upper and outer part. It should not be confounded with a projection on the back of the frontal process of the malar bone below it. The **zygomatic arch**, the **external auditory meatus** and the **mastoid process** can all be readily seen or felt. The upper branch of the posterior root of the zygoma (*supramastoid crest*) running into the posterior part of the temporal ridge can be felt above and behind the external auditory meatus. The **parietal eminence** is used as a landmark but is not a well marked one. To determine it the scalp should be shaved, and it can be more accurately determined when the skull is bared. It is more prominent in young skulls.

In addition to these palpable or visible landmarks and by means of

them we can determine the position of the sutures. The *bregma*, the site of the anterior fontanelle where the sagittal and coronal sutures meet, lies at the intersection of the median line with a vertical line drawn from a point just in front of the external auditory meatus. The *coronal suture* lies in a line from the bregma to the middle of the zygomatic arch. The *pterion* where the frontal parietal and great wing of the sphenoid meet, lies on this line about  $1\frac{1}{2}$  inches behind the external angular process of the frontal and about the same distance above the zygoma. The *sagittal suture* is median and extends between the bregma and the *lambda*. The latter corresponds to the posterior fontanelle and is about midway between the bregma and inion (external occipital protuberance), or  $2\frac{3}{4}$  inches above the latter. The *parietal foramen* is about 4 cm. above the lambda. The *lambdoid suture* joins the sagittal at the lambda and extends thence along a line drawn to the posterior end of the base of the mastoid process, or it may be represented by the posterior two-thirds of a line from the lambda to the apex of the mastoid. The *asterion*, at the postero-inferior angle of the parietal bone where the lambdoid and parieto-mastoid sutures meet, lies on the last-mentioned line  $1\frac{3}{4}$  inches behind the meatus and on a level with the zygoma. The summit of the *squamous suture* is about 2 inches above the zygomatic arch. It should be remembered that the frontal suture, between the two halves of the frontal bone, sometimes persists, and should not be mistaken for a fracture.

The sutures, besides interlocking in a serrated or dentated manner, are bevelled alternately at the expense of the outer and inner aspect. Thus in the coronal suture the frontal overlaps the parietal above and is overlapped by it below. In injuries to the skull *diastasis* or separation of the bones at the sutures occurs in but a very small percentage of cases and then usually in connection with an extensive fracture. It is naturally more common in young than in adult skulls. The squamous suture is the one where diastasis is most common, or when associated with fracture, the sagittal and coronal sutures. The *suture membrane* in young skulls is thick and vascular so that a surface inflammation may travel through it to the internal surface of the cranium and *vice versa*. In *hydrocephalus* the sutures, especially those around the parietal bone, become widely separated and the fontanelles form large openings whose closure is much delayed. The *posterior fontanelle* is normally closed at birth and the *anterior* during the second year, up to which time it acts as a safety valve for the rapidly varying intracranial pressure. It may persist much longer, even to adult life.

As the sutures with their membranes allow the rapid growth of the skull their premature closure prevents the growth of bone in a line at right angles to them. This causes a deformity in shape of the skull or, if more general, a small size (*microcephalus*) of the skull which may be the cause or the result of arrested brain development or idiocy. If it be the cause of idiocy *microcephalus* calls for *craniectomy* to allow for the growth of the brain. Such premature ossification may be due to rickets.

The sutures may assist slightly to break the force of shocks and diminish the liability of fracture, hence the latter would seem more likely to follow a slight injury after the closure of the sutures, which occurs at varying periods after middle life. This closure begins, as in the long bones, at the end of the suture last ossified, *i. e.*, near the fontanelles and occurs first in the sagittal, last in the squamous suture. It is said to begin when the weight of the brain ceases to increase and may be complete by the age of 80 (Tillaux).

The *Wormian bones* occur in varying numbers and sizes along the sutures, most often in the lambdoid suture, and may be mistaken for fragments due to fracture. One of these bones, the *epipteric bone*, is found at the pterion and usually joins the great wing of the sphenoid, of which it may be thought to be a broken fragment. It may be met with in trephining for the middle meningeal artery.

In *craniotabes*, ascribed to rickets or inherited syphilis, the skull is deformed by the premature ossification of the sutures, the occiput is flattened by the pressure of the heavy head resting largely on this part, and the upper part of the occipital and adjacent parts of the parietal bones are thickened, with here and there a thinning on the inner surface, so that in places a mere shell of bone or an entire absence of bone may exist.

**Conditions Depending upon Errors of Development.**—The frontal, parietal, squamous portion of the temporal and the part of the occipital above its highest curved line are formed in membrane, the base of the skull in cartilage. The entire absence of that part formed in membrane is occasionally found as an anomaly. The squamous portion of the occipital bone is ossified from four centers, a pair above the highest curved line and a pair below. The upper pair may form a separate bone, the *interparietal bone* of the lower vertebrates, and the suture between this and the part below should not be mistaken for a fracture. More commonly there persist two lateral fissures, as at birth, or median fissures between the lateral centers, and these fissures also should not be mistaken for fractures.

Certain tumors of congenital origin, containing cerebral contents and called *cephaloceles* or "cerebral herniae," occur as the result of defective development. They are usually situated in the median line and most often in the occipital, next in frequency in the naso-frontal region. *Occipital cephalocele* generally occur through a median fissure in the occipital bone, either above or below the external occipital protuberance; anterior or *sincipital cephalocele* through the naso-frontal suture. More rarely such tumors occur through other abnormal apertures, especially at the base of the skull. When the sac of a cephalocele, which is formed by the outer cranial membranes, contains cerebro-spinal fluid alone the tumor is called a *meningocele*, when it contains brain substance an *encephalocele*. A *hydrencephalocele* is an encephalocele containing a cavity filled with fluid which is often connected with the cerebral ventricles.

The *parietal fissure* is a narrow gap extending from the parietal

eminence to the sagittal suture about an inch in front of the lambda. It is often seen about the fifth month of foetal life as a cleft between the radiating ossific spicules but it usually closes. When present on both sides the lozenge-shaped gap is known as the *sagittal fontanelle*. The fissure should not be mistaken for a fracture.

### Construction and Lesions of the Bones of the Cranial Vault.

In the adult these bones are composed of compact *outer and inner tables* and an intervening cancellous-like layer, the *diploë*. This is not present in children's skulls and does not form until about the tenth year. The *blood supply* of these bones is contained largely in the diploë which receives but little blood from the vessels of the pericranium, more from those of the dura. Some of the consequences of this we have already seen (p. 22). The veins of the diploë empty into both the dural sinuses and the surface veins. As the vessels of the diploë communicate with those of the dura and the dural sinuses, inflammatory lesions of the bone may extend to the sinuses and lead to sinus thrombosis, with the danger of pyæmia, or to the dura and cause pachymeningitis.

Inflammatory lesions of the bones commonly lead to *caries or necrosis*, which is fairly common on the vault of the skull and most often involves the frontal and parietal bones. Owing to its poorer blood supply and its exposure to injuries the external table is more often involved alone than the internal table. *Syphilis* and *tuberculosis* are not uncommon causes of caries or necrosis of these bones, many cases result from injury, especially when the wound is infected, and but few cases are spontaneous or idiopathic. Besides the special dangers, mentioned above, of sinus thrombosis and meningitis, pus may collect between the bone and dura and cause compression of the brain, but fortunately the collection of pus here is not common. When the disease of bone involves the whole thickness of the skull the pulsations of the brain may be seen or felt in the gap produced. Necrosis and separation of extensive areas, even of the entire vault (Saviard), has been reported. A peculiarity of necrosis of the cranial vault is that no involucrum is formed and the bone is not reproduced. As a rule stripping up of the dura is not followed by necrosis.

The average *thickness* of the bones of the cranial vault is  $\frac{1}{5}$  of an inch but this is liable to wide variation in different parts of the same skull and in different skulls. Thus it is very thin and translucent in the squamous portion of the temporal, the anterior inferior angle of the parietal and in the inferior or cerebellar fossæ of the occipital squamosal; while it is very thick at the occipital protuberance, the mastoid process, the lower part of the frontal bone, and along the ridges that bound the grooves for the superior longitudinal, the lateral and occipital sinuses. Again the inner surface of the cranium is marked by *depressions or grooves*: (1) For the cerebral convolutions, (2) for the dural sinuses, (3) for the meningeal arteries (especially the middle

meningeal) and (4) for the Pacchionian bodies. Hence the inner and outer tables of the skull are not parallel with one another.

These facts should be borne in mind in trephining. The pin of the trephine should not be made to penetrate over  $\frac{1}{8}$  of an inch and in many regions  $\frac{1}{16}$  of an inch. The instrument should not be applied over the course of the sinuses, over the position of the frontal sinuses (often of large size in the aged) nor over the position of the middle meningeal artery unless it is desired to expose these parts. As the suture membrane blends with the dura the trephine should not be applied over the sutures for fear of wounding the dura. From time to time the groove made by the trephine should be tested in its entire circumference by a probe to see if it is through where the bone is thinnest. The bleeding in a trephine wound comes almost exclusively from the diploë.

The skull presents certain stronger *ridges* or *buttresses* where the bones are thicker or stronger and between which they are thinner and more readily fractured. These buttresses pass from the vault to the base at the foramen magnum and serve to unite the two parts into one solid framework. Thus one buttress is represented by the median part of the frontal, the ethmoid, the body of the sphenoid and the basilar portion of the occipital. This *anterior buttress* is continuous along the middle line of the vertex with the *posterior buttress* which passes through the occipital protuberance and crest to the foramen magnum. Two *lateral buttresses* exist, the anterior represented by a

FIG. 2.

Preparation of skull, showing the principal arches of strength or buttresses of resistance. (THOMPSON, *i. e.*, after DOLBEAU and FÉLIZET.)

ridge of bone from the vertex to the exterior angular process of the frontal and thence through the great wing to the body of the sphenoid, the posterior running through the parietal eminence, mastoid process, posterior part of the petrous bone and the jugular process to the occipital condyle.<sup>1</sup>

The bones of the skull and the skull as a whole are elastic. This elasticity is greater in the infant than in the aged but even the adult skull is less brittle than commonly supposed. The yielding character of the *infant's skull* is shown in the artificial deformity of the flat-headed Indian, produced by pressure, and it has been asserted (Guéniot) that in infants considerable deformity may be produced by the weight of the brain, by allowing them to lie always upon one side. In addition in the infant there is much cartilage and membrane between the bones. Hence the skull of an infant is not easily fractured. The probable effect of a blow is to indent the skull. During delivery the infant's skull, most often the parietal bone (right parietal in L. O. A. presentations) may be flattened by pressure against the sacral promontory or by the use of the forceps. Though a hemorrhage (*cephalhaematoma*) often occurs beneath the indented area real fracture is rare.

### Fractures of the Skull.

Besides its elasticity the following anatomical conditions of the skull lessen its liability to fracture, the rounded form favoring glancing blows, the density and mobility of the scalp, the composition of the skull by a number of bones separated by sutures and suture membranes which act to a slight extent as buffers, and the mobility of the head on the spine.

Although as a rule the entire thickness of the bone is involved in fractures of the skull yet the *external table alone* may be broken or even depressed into the diploë or into the frontal sinuses. More rarely, the *internal table* may be fractured without injury of the outer table. The latter injury can only rarely be diagnosed by the symptoms (vomiting, convulsions, etc.). Fracture of the *internal table alone* can be explained and illustrated as follows: An injury causing fracture tends to flatten out the skull over the area where the violence is applied and is like bending a barrel hoop so as to straighten it. Like the barrel hoop it gives way first on the inner or concave surface and if the force is not continued this surface alone may be broken. For the same reason in complete fractures the inner table is fractured first. In addition this *inner table* is *most extensively fractured* in most cases for (1) it is thinner and more brittle (hence called the "vitreous table"), (2) the force as it travels from the outer table through the diploë to the inner table passes in a radiating manner so as to reach the inner plate in a more diffused form, (3) the inner table is a part of a smaller circle and (4) as the force tends to flatten out the arch the

<sup>1</sup> Dupuy and Reclus, Vol. III., p. 461.

bony particles of the outer table are forced together and those of the inner table asunder.

In general, **fracture of the vault** occurs from a given violence when the limit of its elasticity is exceeded, as illustrated in the straightening of a barrel hoop. Fractures of the vault are due to *direct violence* and usually occur at the point where the force is applied. When a considerable force is applied over a limited area this area of the skull is usually depressed. When it is applied over a large surface (as in falls from a height) the entire globe of the skull is compressed or flattened in the direction in which the force acts, and lengthened or pulled apart in a direction at right angles to this. Two forms of fracture may result: (1) A "**compression fracture**" at the point where the skull is pressed together by the direct violence, and (2) a "**bursting fracture**" where the skull has been lengthened and pulled asunder. The latter form is due to indirect violence and occurs more often at the base than on the vault of the skull.

The **symptoms and danger** of fractures of the vault depend very largely on the concomitant brain lesions: (1) Concussion, (2) contusion of the brain, (3) intracranial hemorrhage. Fractures of the *temporal region* are in general more serious than similar fractures of the rest of the vault, for the *middle meningeal artery* is often injured and the resulting hemorrhage causes compression of the brain. The escape of *cerebro-spinal fluid* from a fracture of the vault is not common, though it has been observed in compound fractures and in simple fractures in children (resulting in a fluctuating tumor beneath the scalp). It indicates injury of the dura.

It is interesting to note how the construction of the skull resists the fracturing force in many ways. A blow on the vertex in the parietal region tends to drive the upper borders of the parietal bones inward and the lower borders outward. The latter tendency is resisted by the overlapping great wing of the sphenoid and the squamous bone. The latter is buttressed by the zygomatic arch and this in turn by the malar and the bones of the face, hence the pain in the face said to be felt in falls or blows on the top of the head. When the frontal suture exists a tendency of the lower part of the frontal bone to be forced outward in blows on the median parts of the frontal is similarly resisted by the overlapping anterior inferior part of the parietal and the great wing of the sphenoid. A blow on the upper part of the frontal bone is transmitted to the parietal on which this part of the frontal bone rests owing to the bevelling of the upper part of the coronal suture. Blows on the occiput are less safeguarded by anatomical arrangements, except by its articulation with the elastic vertebral column. *Gaseous tumors* beneath the scalp have been described as a sequel to fractures of the skull in which one of the cavities containing air has been involved in the fracture, *i. e.*, the various sinuses, mastoid cells, etc.

**Fractures of the base** may be due to (1) direct violence, (2) indirect violence, and (3) extension of a fracture of the vault. Fractures of the base by *direct violence* occur in cases where a foreign body is

forced through the orbital, nasal or pharyngeal roof or through the nape of the neck in the posterior fossa. They are not common. One form of fracture of the base by *indirect violence* is illustrated by the fracture of the cribriform plate of the ethmoid or the orbital plate of the frontal by a blow on the root of the nose or the lower part of the frontal bone; and by the fracture of the glenoid fossa by the condyle of the jaw driven violently upward, as in falls or blows on the chin. In this manner the condyle has been actually thrust into the cranial cavity (Chassaignac). Again, in falls upon the buttocks, less often upon the feet or knees, the force has been transmitted along the vertebral column, especially when it is kept rigid by muscular action, and has resulted in the fracture of the base in the occipital region, often in a "ring fracture" around the foramen magnum. A similar fracture may possibly result from a blow on the head just as the handle of a hammer may be driven in either by a blow on the end of the handle or by one on the head of the hammer.

The mechanism of the majority of fractures of the base has been much discussed. The former theory that many were the results of *contrecoup*, or a focusing of the force at the opposite pole to that struck, has been abandoned. Possibly a very few cases may be so explained though perhaps better as "compression" or "bursting" fractures. Aran and others showed that very many fractures of the base were fractures by *irradiation*, *i. e.*, the result of fractures of the vault spreading to the base by the shortest route irrespective of the sutures, hence fractures of the frontal region spread to the anterior fossa, those of the parietal region to the middle fossa and those of the occipital region to the posterior fossa. This was especially the case in linear fissures, the result of diffused violence, as in falls upon the head. In general when the violence is not excessive Felicet found that these fractures seem to run in the weaker areas between the ridges or buttresses (see p. 29). These explanations do not fit all cases or even the majority, as well as does that of "compression" and "bursting" fractures (see p. 31). As seen above the latter are indirect fractures and probably comprise most of the fractures of the cranial base. Fractures due to bursting (*i. e.*, most fractures of the base) run parallel to the axis of pressure, those due to compression run at right angles to this axis. Fractures of the base run in the direction of the violence that inflicts the injury or parallel to it. Hence, given the direction of the force and the point struck, we can fairly well predict the course of a fracture of the base. Bursting fractures are most likely to occur where the skull is weakest which is at the base, owing to the numerous foramina, etc. (Figs. 3 and 4).

In fractures of the base there is usually a discharge of *blood* and often of *cerebro-spinal fluid* externally. In the majority of basal fractures the *petrous bone* is involved and especially that part which is weakest, which lies in the plane passing through the middle ear, the internal ear and the internal auditory meatus. In such cases the tympanic membrane is commonly ruptured and this allows of the escape

PLATE I.

FIG. 3.

FIG. 4.

## Illustrating lines of bursting force in basal fractures. (Wahl.)

FIG. 5.

Interior of the base of the skull covered by dura, showing the sinuses, nerve exits and tentorium. Cranial nerves are numbered in Roman figures. (Merkel.)

of blood from the ear, a symptom so common in fractures of this region of the base. This blood may be derived from the vessels of the tympanum and its membrane or from an intracranial source, sometimes from the rupture of one of the sinuses about the petrous bone. If the membrane is not ruptured the blood may pass through the Eustachian tube and escape at the nose or mouth. In addition to bleeding from the ear the flow of cerebro-spinal fluid is sometimes observed. This occurs when the dura and arachnoid, or their tubular prolongation in the internal auditory meatus, are torn by the fracture, which connects the subarachnoid space with the tympanum whose membrane is lacerated. A free serous discharge may occur from the ear after an injury to the head, without fracture. It escapes through a rupture in the tympanic membrane and may be derived from the mastoid cells or it may be blood serum.

In fractures of the *anterior fossa* the blood escapes into the nose, mouth or orbit. In the latter case it produces a subconjunctival ecchymosis, rarely an exophthalmus. Bleeding into the nose may run back into the mouth and in bleeding either into the mouth or nose the blood may be swallowed and subsequently vomited. When bleeding from the nose or mouth occurs as the result of a basal fracture the latter involves the cribriform plate or the body of the sphenoid. In bleeding from the nose the greater part of the blood probably comes from the torn mucosa of the nasal roof. If there is a discharge of cerebro-spinal fluid from the nose there must be a laceration of the nasal mucosa and of the dura and arachnoid. In fracture of the base in the *posterior fossa* of the skull the blood may appear as an extravasation about the mastoid process or the nape of the neck.

The symptoms and serious nature of basal fractures depend upon the concomitant *intracranial lesions*. *Meningitis*, due to infection of a fracture of the base which opens into a cavity connected with the air, is rare as a cause of death as compared with the intracranial lesions due to the injury. The base of the skull is rather *inaccessible to operations* on account of its location.

Owing to a lack of reparative vitality, repair after fractures of the skull is very slow and bony union occurs only when the fragments are separated by a very small interval. The new bone is produced mostly by the diploë and more by the dura than by the pericranium. When there is any considerable loss of substance the opening is not filled in with bone save for a narrow strip around the edge. After recovery from diastasis in a child the growth of bone is not interfered with.

## THE CONTENTS OF THE CRANIUM.

### The Cerebral Membranes.

The tough fibrous **dura** may be divided into an outer **periosteal layer** and an inner or **supporting layer**. This corresponds to its twofold function, on the one hand as an endosteum and on the other as a

protective covering of the brain. These layers are inseparable over the greater part of their extent, but the inner separates from the outer layer to form the *cranial sinuses* and the *processes*, like the *falk* and *tentorium*, which help to support and protect the brain. (See Fig. 1.)

The adhesion of the outer layer to the bone increases with age and in chronic inflammation of the bone or the dura, but is less intimate in acute inflammations. It varies in different parts of the skull. Over the vertex and, according to Tillaux, particularly in the temporal fossæ the dura is comparatively loosely attached, except along the sutures where it is more adherent. This loose attachment allows a probe to be passed a considerable distance between the bone and the dura, if the sutures are avoided, and large extravasations of blood or pus may occur here and lead to compression of the brain. Such extravasations are often limited to one bone by the adhesion along the suture lines, but not necessarily, especially in the case of purulent collections. The adhesion of the dura to the bone is largely due to the passage of small blood vessels from the meningeal vessels of the former to nourish the bone. The bone can live however if the dura is stripped off and after loss of bone the loss is not repaired by the dura. In the majority of traumatic cases the cause of cerebral compression lies outside the dura in the epidural space or is due to the bone itself.

As pointed out by Sir C. Bell the *dura* of the vault may be *separated from the bone* by a blow and if this occurs during life the corresponding epidural area is occupied by a clot from the rupture of many small vessels that pass from the dura to nourish the bone. If a larger vessel is ruptured the *hemorrhage* may gradually strip off more and more of the dura so that a clot is formed which gradually causes local or general symptoms of *compression*. The stripping up of the dura may be demonstrated on the cadaver by striking a blow and then injecting the blood vessels.

The vessel which by its rupture is most often (85% more or less) the *cause of serious or fatal epidural compression* is the *middle meningeal artery*, in the temporal fossa. This is the cause of the more serious results of fracture in this region. This vessel is for the most part closely wrapped by the outer layer of the dura so that it is ruptured in any tear of the latter, in fracture of the skull. It may also be torn without fracture, for in the great wing of the sphenoid and the antero-inferior angle of the parietal it is often lodged in a bony canal or a groove whose open side is smaller than that of the artery so that if by a blow the dura is here stripped from the bone the artery is torn at the point where the canal or deep groove prevents it from being stripped back with the dura. When after a blow over the position of this vessel symptoms of compression, not present at first, come on after an interval and gradually increase rupture of this artery or some of its branches is probable. As it lies in part over the cortical *motor area* *motor paralyses* are likely to occur from local compression. As such cases get progressively worse and end fatally, operation with turning out the clot and plugging or tying the vessel is imperatively demanded.

Hence the importance of knowing the position and course of this vessel. (See Fig. 7.) The trunk of the artery passes outward and forward for a short but variable distance from the foramen spinosum, through which it enters the skull. It has *two main branches* of which the larger *anterior* one runs upward and forward across the antero-inferior angle of the parietal bone and continues in a groove a little behind the coronal suture, giving off branches which run upward and backward. The *posterior branch* runs backward across the squamous bone and then upward and backward over the posterior part of the parietal bone. Although it may be possible by a single trephine opening to expose both branches of the artery yet such an opening must be low down on the temporal fossa and below the common site of injury of the vessel, which is in the anterior branch near the pterion, where the groove is often very deep or converted into a canal. When the groove is so arranged fracture here without laceration of the artery would hardly be possible and this thin part of the skull is particularly liable to be fractured. If we trephine and ligate the artery too low an anastomotic branch from the orbit may join the artery above the point of ligation and below the point of rupture and thus continue the hemorrhage.

To expose the anterior branch of the middle meningeal artery a trephine opening or bone flap is made just behind the pterion (see p. 26); or two fingers' breadth above the zygoma and a thumb's breadth behind the frontal process of the malar bone (Vogt); or 3-4 cm. behind the latter point on a level with the supraorbital margin (Krönlein). As the artery lies enclosed in the firm dura or in the bone the chance of spontaneous arrest of bleeding is slight.

At the *base* of the skull the *dura* is closely *adherent* to the bone so that epidural extravasation can scarcely occur, and in fractures of the base the dura is likely to be torn, allowing the escape of cerebro-spinal fluid. The dura smoothes over some of the inequalities of the base and passes out through the foramina of the skull with the cranial nerves to become continuous with the nerve sheaths as well as with the pericranium on the outer surface of the skull. Its *inner surface* is smooth owing to the layer of flat endothelial cells which covers it.

The **subdural space**, or the potential interval between the dura and the arachnoid, contains a small amount of *fluid* and probably serves to prevent friction of the surface of the brain during its movements, like the pleural and other serous sacs. The hemorrhage in *pachymeningitis hemorrhagica* occurs in this space, into which a considerable effusion may occur without marked symptoms on account of its wide diffusion. Following an injury extravasations of blood into this space are very common and the blood so effused is liable to shift its position and perhaps suddenly cause dangerous symptoms by gravitating to the vicinity of the pons, cerebellum and medulla. Similarly, during *operations* upon the brain, blood, pus or irrigating fluid may enter this space and gravitate toward the medulla or spinal canal. Hence care should be taken in evacuating and irrigating cerebral abscesses to avoid the passage of the fluid into this space and to secure its escape extracranially.

The subdural space communicates with the abundant lymphatics of the dura and from the latter pathogenic organisms may invade this space. Normally the *inner surface* of the dura is not connected with the arachnoid except by a few and very delicate processes, hence on opening the dura any adhesions which prevent the probe or finger passing freely between it and the brain are pathological.

The *fibrous folds* formed by the reflection of the *inner or protective layer* of the dura (falx cerebri, tentorium cerebelli, etc.) are of little surgical interest but they are important in preventing the compression of the two hemispheres by each other, and of the isthmus of the brain and the cerebellum by the cerebrum.

**The sinuses of the dura** are formed by the separation of the inner from the outer layer on the surface or by the separation of two folds of the inner layer on the folds or processes of the dura. (See Fig. 1.) They are lined by an *epithelial layer* continuous with the inner layer of the veins. Their walls are rigid and *non-collapseable* so that when wounded bleeding is not spontaneously arrested. Certain sinuses are of especial surgical interest and their position is of importance because in certain operations we wish to avoid them, in others to expose them (Fig. 5).

**The superior longitudinal** or sagittal sinus extends in the median line from the foramen caecum anteriorly to the torcular Herophili, opposite the external occipital protuberance, posteriorly. As the torcular is usually to the right of the median line the posterior and larger part of the sinus is also rather more to the right of the median line. Through the *foramen caecum* it communicates with the veins of the nasal mucosa, hence epistaxis may directly relieve cerebral congestion and infective organisms from lesions of the nasal septum may thus enter the sinus. It also communicates with the scalp by the emissary veins passing through the parietal foramina so that it may become infected from erysipelas or other septic diseases of the vertex. This sinus receives the veins from the median and upper surface of the cerebrum and communicates with the basal sinuses through the anastomosis of the superior cerebral with the middle cerebral and Sylvian veins. As the blood of the superior longitudinal sinus usually passes into the right lateral sinus and that of the straight sinus into the left lateral sinus, it follows that the right lateral sinus is usually the larger and receives the blood from the surface of the brain while the left sinus drains the central ganglionic portions.

**The course of the lateral sinuses** is represented by a line from the external occipital protuberance to the upper margin of the external osseous meatus or the base of the mastoid process. (See Fig. 9.) It is usually slightly convex upwards and crosses the asterion, from whence to the jugular foramen it is called the **sigmoid sinus**, on account of its crooked S-shaped course. The sharp downward and inward bend, or *genu*, of the sigmoid sinus on the mastoid bone is convex forward. It reaches forward to a point  $\frac{1}{8}$  to  $\frac{1}{4}$  of an inch behind a coronal plane through the posterior border of the external osseous meatus and is on a level with the upper part of the meatus. The *genu* on the right

side extends slightly further forward and outward than on the left and this fact may possibly account for the supposed greater frequency of intracranial complications following otitis media on the right side. The genu of the sigmoid sinus receives groups of veins from the tympanum and the mastoid antrum and cells, through which infection may spread to the sinus and cause thrombosis.

**The course of the sigmoid sinus,** where it is accessible to operation, corresponds to two lines ; the upper and more superficial part to the posterior  $\frac{2}{3}$  of a line from the asterion to the upper margin of the external osseous meatus, the vertical part to the upper  $\frac{2}{3}$  of a line from the parieto-squamo-mastoid junction (or the middle of the base of the mastoid) to the tip of the mastoid (see also Fig. 7). An opening may be made into the genu, the part of the sinus most often affected, at a point half an inch behind the posterior wall of the bony auditory canal between the levels of its roof and floor. Between these levels the upper and more superficial part of the sinus is  $\frac{1}{4}$  inch (sometimes as little as  $\frac{1}{12}$  inch) from the surface and is thus more superficial than the antrum, while its lower part lies more deeply.

The sigmoid sinus is connected with the surface veins through two emissary veins, the mastoid and the posterior condylar. The **mastoid vein** joins the occipital and through this the deep cervical, or occasionally it joins the posterior auricular. It may become thrombosed from sinus thrombosis or its foramen may give vent to extradural pus in the cerebellar fossa. The **posterior condylar vein** is the larger and more constant of the two, contrary to what is usually stated. It joins the deep veins at the back of the neck and its foramen may drain extradural pus in the bottom of the cerebellar fossa, setting up a deep inflammation or abscess in the upper part of the back of the neck which causes swelling and tenderness on pressure here. These two emissary veins and the occipital sinus may convey infective matter from the lateral and sigmoid sinuses to the heart and lungs so that ligation of the internal jugular vein does not afford complete protection against this accident.

The upper and posterior end of the sigmoid sinus lies at the junction of the middle and anterior thirds of the *cerebellum* so that the latter may be exposed in front of the sinus, though preferably behind it. The *parieto-squamo-mastoid junction* corresponds to the point where the superior petrosal joins the sigmoid sinus and where the upper border of the petrous joins the mastoid bone.

**The cavernous sinus** extending from the sphenoidal fissure to the apex of the petrous bone receives and is, as it were, the continuation of the *ophthalmic vein*. The fact that the latter anastomoses with the facial through the nasal vein explains why an inflammation near the facial vein, like a carbuncle of the upper lip, is more serious than a similar condition on the lower lip, as the former may extend along the veins and set up a cavernous sinus thrombosis. This sinus also communicates with the *pterygoid plexus* by means of the ophthalmic and Vesalian veins through which infective matter may pass from one to the other. The intimate relation between the *carotid artery* and the

cavernous sinus accounts for the fact that *arterio-venous aneurism* has followed injury of these parts. In such cases the orbital cavity is distended with a pulsating tumor consisting of the dilated ophthalmic veins which protrude the eyeball.

As the dural sinuses are rigid, non-collapsible, ever-patent tubes and the jugular veins into which they empty are alternately distended in expiration and collapsed in inspiration this *aspiration* would involve the sinuses unless there were some *mechanism to prevent it*. If the sinuses were thus aspirated and the blood of the brain suddenly propelled forward to compensate for that withdrawn there would be a disturbance of brain function, a sudden faintness or lack of brain power on each deep inspiration. The entire sinus arrangement ensures a *regular even flow* as seen in the entrance of the middle and posterior cerebral veins obliquely into the longitudinal sinus against its current, thus damming it back,<sup>1</sup> and especially in the *trap-like passage* of the sigmoid sinus into the jugular bulb. The roof of the lowest portion, near the end of the sigmoid sinus, is on or below the level of the floor of its entrance into the jugular bulb and the roof of the latter is much above the whole of the lower end of the sigmoid sinus so that an arrangement like a plumber's trap is formed to prevent aspiration of the sinus. This aspiration is further prevented by the entrance of the *inferior petrosal sinus* into the jugular bulb so that this sinus alone, if any, would feel the effects of aspiration. Furthermore by pouring its blood into the jugular bulb from a large reservoir, the cavernous sinus, there is no absolute collapse of the internal jugular with the consequent difficulty in reestablishing the flow.

Between the two layers of the dura and occupying a depression on the upper surface of the apex of the petrous bone and the adjoining cartilage filling the middle lacerated foramen, is the crescentic **Gasserian ganglion**. This with the roots of two of its branches, the superior and inferior maxillary divisions of the fifth nerve, is sometimes removed for intractable neuralgia. The best *method of operation* is the osteoplastic Hartley-Krause method by which an  $\Omega$ -shaped flap of bone and soft parts, having its base on a level with the zygomatic arch, is turned down exposing the dura. The latter is then separated from the floor of the middle fossa of the skull until the two branches named above are exposed and traced up to the ganglion. To expose the latter the outer layer of the dura must be divided. Its close relation to the internal carotid artery and the cavernous sinus as well as to the middle meningeal artery must be borne in mind, and the latter artery may also give trouble in the bone flap. A small vessel accompanying the inferior maxillary nerve has occasionally caused troublesome hemorrhage.

The delicate arachnoid is closely applied to the pia, over the top and sides of the head, but does not dip in between the convolutions. The subarachnoid space is scarcely recognizable over the upper surface, though present, while over the posterior two-thirds of the base (in the

<sup>1</sup> For further interesting particulars consult Macewen, Diseases of the Brain and Spinal Cord, p. 35.

posterior and middle fossæ) it is large and contains the larger part of the cerebral cerebro-spinal fluid. The latter serves as a water bed for the important parts of the brain resting upon it, while the less important frontal lobes rest directly upon the bone, covered by dura. This arrangement of the fluid protects the posterior parts of the base of the brain from the effects of injury, either direct or by contrecoup, while the base of the frontal lobes is not infrequently injured by coming in violent contact with the irregular orbital plates. The cerebro-spinal fluid differs from blood serum in its very small percentage of albumin. The cerebral and spinal subarachnoid spaces communicate freely with each other through the foramen magnum and with the cavity of the cerebral vesicles through the *foramen of Magendie*, in the lower part of the roof of the fourth ventricle. Hence the cerebro-spinal fluid may also serve to equalize the intra-cranial pressure by being partly forced out from the ventricles through the foramen of Magendie when the nerve centers in the walls of the ventricles are congested and down into the spinal canal if the general intracranial pressure is increased, as in cases of congestion from irregularities in the blood circulation. In case the foramen of Magendie is blocked by a tubercular deposit or the pressure of a cerebellar tumor fluid may accumulate in the ventricles and result in internal hydrocephalus. *Lumbar puncture* as a diagnostic and therapeutic measure depends upon this intercommunication and flow of the cerebro-spinal fluid from one part to another. In operations on the base of the brain, or on a spina bifida, etc., the draining away of cerebro-spinal fluid may deprive the medulla of its water bed and cause it to rest directly upon bone, so as even to interfere with its functions.

The subarachnoid space is continued around the *optic nerve* in the orbit where it may even become cystic by being shut off from the rest of the space. Over the other cranial nerves the arachnoid is continued only a short distance and becomes fused with the nerve sheath, but fluid injected into the subarachnoid or subdural space passes along the nerves as far as the limbs. Without any direct channel fluid may also pass from the subarachnoid to the subdural space and even from the former into the longitudinal sinus through the Pacchionian bodies, which are arachnoid villi and project in some cases into the sinus. The arachnoid is not considered as an entity in the pathology of meningeal inflammation.

The intimate relations of the *pia* and brain, the former closely covering the surface and dipping into the substance of the brain as an investment of its blood vessels, shows that a certain degree of encephalitis is necessary with lepto-meningitis. The *lymphatics* of the pia open into the subarachnoid space.

Little need be said of the brain itself, apart from the facts of cerebral localization and crano-cerebral topography, except that surgically it is a large soft vascular mass that does not completely fill the cranial cavity and hence may be injured by shaking or by being thrown about and colliding with the cranial walls.

As a result of injury to the head, symptoms of shock may be present which are known as **concussion** of the brain. It is supposed that no visible lesions of the brain are thereby produced and the symptoms do not long persist. From a more severe injury the soft brain, especially its cortex, may suffer **contusion** (or laceration) or the soft brain may be compressed within its unyielding walls by a depression of a part of the walls or an extravasation of blood or pus within them. In contusion of the brain the cortex of the base is most often exposed to injury, but as the posterior two-thirds of the base are well protected by its water bed of cerebro-spinal fluid this part is comparatively seldom injured while the frontal lobes are often injured.

The **blood supply** of the brain is most abundant, so much so that the *carotid* may be ligated without effect on the brain though cerebral complications have occasionally followed this operation. In fact both carotids have been ligated without marked cerebral disturbance, provided an interval of a few weeks has elapsed between the two operations. After ligation of one or both carotids or in case of other disturbance of the cerebral circulation the latter is equalized by the anastomosing circle of Willis. The effects of the heart's systole on the brain are diminished by the tortuosities of the arteries (internal carotid and vertebral) before entering the cranial cavity, but the brain *pulsates* synchronously with the systole of the heart. This pulsation may be seen or felt on the dura unless the intracranial pressure is increased, when the pulsation is diminished or absent. This pulsation may be transmitted to the overlying soft parts where the bone is wanting on account of injury, disease or operation. The *circulation* in the smaller cerebral arteries is *terminal*, i. e., without anastomosis, so that plugging by an embolus causes blood stasis and coagulation necrosis in a cone-shaped area having its base on the surface. Wounds of the brain from injury or operative incision bleed freely, but this bleeding is readily checked. The brain *weighs* on an average  $49\frac{1}{2}$  oz. in the male and 44 oz. in the female.

### Localization of Cerebral Functions.

The cortical areas whose function is accurately known comprise : (1) The *motor area*; (2) the *speech areas*; (3) the *visual areas*; (4) the *auditory area*; (5) the *area of the sense of smell and taste*. The precise limit of these areas is not accurately known and one area may fuse with another. It is most important to know the position of these centers as a guide in diagnosing and operating on lesions of the cerebral cortex (Figs. 6 and 7).

The **motor area** comprises the cortex of the anterior and posterior central convolutions, bordering the fissure of Rolando, and the cortex immediately adjacent to them, especially the paracentral lobule on the mesial surface. In the upper third of the Rolandic area is the area for the **lower extremity**, in the middle third that for the **upper extremity**, and in the lower third that for the **face and tongue** (facial and hypoglossal nerves). In the areas for both extremities the centers for the

proximal portions are in the anterior and upper part of the area (*i. e.*, in the anterior central convolution) those for the distal portions in the

FIG. 6.

A

Localization of function on the cerebral cortex ; external surface. (After STARR.)

posterior and lower part of the area and those for the intervening portions in the space between. In the lower third of the motor area the

FIG. 7.

B

Localization of function on the cerebral cortex ; mesial surface. (After KOCHER.)

centers for the upper facial muscles lie above and in front, that for the platysma above and behind and that for the mouth and tongue below.

The movements of the **eyes and head** are controlled by the cortex of the posterior part of the second frontal convolution, irritation of which causes conjugate movements of the head and eyes to the opposite side.

In the *paracentral lobule* from before backward we find centers for the arm, shoulder-girdle, trunk, pelvis, leg and foot. Here the centers for both extremities so merge into one another that both may be paralyzed by a single lesion.

It is to be remembered that each hemisphere controls movements mainly on the *opposite side* of the body, but to a slight extent also on the same side. This accounts for a large amount of the recovery after destruction of the centers of one side, especially those of the distal movements of the limbs. This recovery is explained by others by the fact that though there is a focus for the movement of a particular part, like the thumb, it is also represented with diminished intensity over the surrounding cortex. Hence to totally paralyze a given part a considerable amount of cortex must be excised.

**The speech areas**, four in number and in kind, are in the right hemisphere in right-handed persons and in the left in left-handed persons. The **motor speech center** lies in the posterior part of the third frontal convolution near (just in front of) the center for the muscles of speech (hypoglossal and facial nerves). A lesion of the motor speech center causes *motor aphasia* in which there is loss of a word-forming power although the tongue is movable and consciousness is present.

The **auditory speech center** is in the posterior two-thirds of the first, and perhaps the second, temporal convolution. A lesion here causes "*word-deafness*," a sensory aphasia in which the memory of the sounds of words is lost so that they are not understood, though hearing may be normal.

The **visual speech center** lies in the posterior part of the angular convolution of the lower parietal region. *Word-blindness*, or the loss of understanding of printed or written language, is caused by a lesion here, though sight itself is normal. The power of **writing** belongs to speech but its center is not accurately determined. It is usually lost when the motor speech area is destroyed, but some cases point to its probable location in the second frontal convolution, others to its location near the hand center.

**The visual center** is situated in the occipital lobe, especially in the vicinity of the calcarine fissure. Lesions of this area cause a *half-blindness* of *both eyes*, the blind field of vision being on the opposite side to the lesion and on the same side of the body in both eyes. Central vision is unimpaired and the pupils react normally.

The center of **sensations of taste and smell** is located in the under and inner surfaces of the tip of the temporal lobe but only bilateral lesions produce noticeable symptoms for each lobe is related to both sides of these sensory organs. The same may be said of the center of **sensations of sound** which is located in the first and second temporal convolutions.

According to some a **sensory cortical area** (*tactile and muscular sensations*) is found in the posterior part of the motor area, the posterior central convolution, and the area just behind this, but if present here

this area is not coextensive with the motor area. Motor paralysis of cortical origin is often independent of anaesthesia and when the latter coexists it may be due to a dynamical disturbance and is usually more temporary than the motor paralysis. According to Fernier and others, lesions of the cortex in the falciform lobe, especially in the hippocampal region and the gyrus forniciatus (Horsley), cause more permanent anaesthesia, and this region is connected by association fibers with the motor area. The motor and sensory tracts are separate in the nerves, cord, crus and internal capsule and we would hardly expect them to be found together in the cortex.

A large part of the cortex is thus seen to be wanting in known function. Of this portion Flechsig has described four areas in the adult, not present in the infant, whose structure is similar and differs from that of other parts. These areas lie in the frontal, temporal and posterior part of the parietal lobe and in the Island of Reil and are called *mental or association centers* because they join together the activities of the various organs of sense. These and other unnamed areas of the cortex are probably related to the higher forms of intellectual activity, for the full play of which a general integrity of the whole brain is necessary. But a disease in any one of the parts does not cause the loss of any one mental faculty. Thus very considerable damage or loss of substance has involved the frontal lobes without a serious disturbance of the mental powers.

The function of the *corpora striata* and *optic thalamus* is undetermined. Lesions of them cause no definite symptoms unless they involve the tracts in the internal capsule. The *crura cerebri*, *pons* and *medulla* contain the centers of the cranial nerve nuclei and transmit the motor and sensory tracts to the cord. Hence lesions in them cause cranial nerve palsies on the same side and motor and sensory paralyses of the opposite extremities. Lesions of the *crura* involve especially the third cranial nerve, those of the *pons*, the fifth, sixth and seventh.

The *cerebellum* controls the equilibrium of the body so that a staggering gait and vertigo result from lesions of it, especially of its median lobe.

The *medulla* contains, in addition to the centers named above, the respiratory and vaso-motor centers and the inhibitory center of the heart, also the reflex centers for deglutition, sneezing and coughing, etc.

Upon the above local symptoms we are dependent for our diagnosis of the location of a lesion. In order to be able to expose by operation that part of the brain where the lesion is thus located we must be able to locate certain of the fissures of the brain on the surface of the head.

### Cranio-Cerebral Topography.

1. *The Relation of the Brain as a Whole to the Skull.*—The lower limit of the cerebrum is approximately indicated by a line slightly convex upward, about one third of an inch above the supraorbital margin, crossing the temporal crest half an inch above the external

angular process of the frontal bone, thence somewhat convex downward and forward to just above ( $\frac{1}{4}$  inch) the external auditory meatus and from here to the external occipital protuberance, just above the lateral sinus (see p. 36). Below the latter part of the line lies the cerebellum. Each cerebral hemisphere extends up to the superior longitudinal sinus (see p. 36), just to one side of the median line.

2. As to the fissures the *localization of the fissures of Rolando and Sylvius*, and perhaps also of the *parieto-occipital fissure*, enables the surgeon to expose all the cortical areas whose function is definitely known.

FIG. 8.

Cranio-cerebral topography, showing relation of brain and some of the fissures and convolutions to the sutures and bony landmarks.

**The Fissure of Rolando.**—Measure in the median line the distance between the root of the nose (nasion) and the external occipital protuberance. Half an inch behind the center of this line (or 55/100 of the distance back from the nasion) represents the point where the continuation of this fissure meets the median line. From this point a line drawn downwards and forwards at an angle of 67 degrees with the median line lies over the fissure of Rolando. This is about  $3\frac{1}{2}$  inches long and commences half an inch or so from the median line. In its lower third the fissure becomes a little more vertical than this line. The upper end of the fissure of Rolando may also be found by drawing Reid's base line from the infraorbital margin through the

center of the external auditory meatus and erecting a perpendicular from the posterior border of the mastoid process. Where the latter line reaches the median line gives us the point from which to draw the fissure of Rolando as before. Or it may be drawn from this point to the point where another perpendicular to the base line, just in front of the external auditory meatus, intersects the fissure of Sylvius (Reid). This intersection lies on the anterior perpendicular line about two inches above the external auditory meatus. According to Le Fort the direction of the fissure of Rolando is also represented by a line connecting the uppermost point of this fissure, as determined by either of the preceding methods, with the middle of the zygomatic arch. The lower end of the fissure of Rolando is about half an inch above the fissure of Sylvius and one inch behind the junction of that fissure with its vertical limb. The lower end of the fissure of Rolando is about one inch (28 cm.), the upper end two inches, behind the coronal suture. The upper end is about at the center of the sagittal suture. The two central convolutions take up about an inch on each side of the fissure of Rolando.

FIG. 9.

Cranio-cerebral topography, showing the relation of the fissures of Rolando and Sylvius, the middle meningeal artery and the lateral sinus to the landmarks and sutures of the head.

**The fissure of Sylvius** is represented on the surface by a line from a point (pterion)  $1\frac{1}{4}$  inches horizontally behind the external angular process to a point  $\frac{3}{4}$  of an inch below the most prominent point of the

parietal eminence. The anterior  $\frac{3}{4}$  of an inch of this line represents the *main fissure*, the rest of the line the *horizontal limb*. The short *vertical limb* ascends for an inch just behind the lower end of the coronal suture from the junction of the main fissure with its horizontal limb, or from a point two inches horizontally behind the external angular process. The fissure of Sylvius is about four inches long, its anterior part is just above (Horsley), below or in the line of the squamous suture. Around its hind end lies the supramarginal gyrus to which the parietal eminence fairly accurately corresponds. Below the Sylvian fissure lies the first temporal gyrus. The anterior part of the fissure slants gently, the posterior part more sharply upwards.

FIG. 10.

Superior frontal fissure.

Drawing to illustrate cranio-cerebral topography. (MACALISTER.) Taken from a cast prepared by Professor Cunningham.

The **parieto-occipital fissure** lies  $\frac{1}{8}$  to  $\frac{1}{2}$  of an inch in front of the lambda (Horsley) or where the fissure of Sylvius continued would reach the median line (or a little below this). It separates the parietal and occipital lobes and runs outwards on the external surface of the brain for about an inch.

It may be added that the **coronal suture** lies over the posterior extremities of the three *frontal gyri*, the sulci separating which may be represented as follows: *the superior* by a line drawn backwarp from the supraorbital notch parallel with the median line, *the inferior* by the frontal part of the temporal ridge.

It should be remembered that the sulci and gyri are never precisely alike and that their relations to the surface vary slightly in different individuals, but as we expose a considerable area in most cases, the desired area is sure to be exposed and can be recognized by its relation to the sulci and, in the motor area, by electrical stimulation.

### THE EAR.

The **pinna, auricle or external ear**, is *formed* by a partial fusion of six small tubercles on the skin at the end of the first visceral cleft. In connection with this cleft are developed the Eustachian tube, tympanum and external meatus. A supplemental rudimentary pinna is sometimes formed at the end or margins of one of the lower clefts, appearing congenitally as an irregular mass of fibro-cartilage on the side of the neck. When the fusion of the six tubercles is less complete than usual, a tag-like *supernumerary auricle* may be present on the cheek just in front of the ear, or *fistulae* or *fissures* of the auricle may occur. The more marked congenital fistulae may be due to defective closure of the first branchial cleft. A dermoid cyst of the pinna may result if the opening of such a fistula closes.

The *framework* of yellow *elastic cartilage* gives the ear its essential *shape* which varies greatly in individuals and is largely influenced by heredity. A *haematoma* may occur between the skin and the cartilage of the ear and is most common among athletes, such as football players, boxers, or prize fighters, and among the insane. The resulting deposit and contraction of new connective tissue, especially when the accident recurs as in the left ear of prize fighters, causes the markings of the ear to be obliterated and replaced by a wrinkled flattened surface, a condition sometimes known as *prize fighter's ear*. Curiously enough a fine antique bronze statue of a boxer discovered in Rome in 1885, and some other antique statues, show this same condition of the left ear.

The auricle is so *firmly attached* to the skull by the cartilaginous meatus that the body of average weight may be lifted from the ground by the ears. The removal of the pinna is followed as a rule by comparatively little diminution of hearing. As there is but little subcutaneous fatty tissue between the skin and the cartilage the *blood vessels* of the ear are not well protected against cold so that the ear is often the seat of gangrene from frost bite. As the trunk of the *posterior auricular artery* occupies the angle between the auricle and the mastoid process we carry the *incision* to expose the antrum or mastoid process a little behind this angle.

The **external auditory meatus** in the adult is about 1 inch in *length*, of which  $\frac{1}{3}$  belongs to the cartilaginous and  $\frac{2}{3}$  to the bony portion.

In the infant the bony part is a mere ring and the cartilaginous portion is relatively longer and nearly straight, which renders an examination easier. Owing to the obliquity of the drum membrane the inferior and anterior walls are longer than the superior and posterior respectively.

Its general direction is inward and forward, but in passing from without inward the outer end slopes upward, the inner part downward so that the center of the canal is the highest point of an upward convexity. Furthermore the outer part inclines sharply forward and then bends backward while the bony or inner portion inclines gently forward again. Hence to straighten the canal to introduce a speculum and be able to see the entire membrane the pinna is pulled upward to straighten the upward curve and backward to straighten the antero-posterior curves. The external meatus, the promontory, the cochlea and the internal meatus lie nearly in the same line.

FIG. 11.

Vertical section through the external auditory meatus and tympanum, passing in front of the fenestra ovalis. (GERRISH, after TESTUT.)

**Diameters.**—The outer end is elongated vertically, the inner end slightly transversely, while the middle part is circular. On these differences depend the two forms of *ear specula*, the one round which fits the narrow circular median part of the canal, the other oval which fits and fills the outer part of the canal. The latter admits more light at the outer end, the former has a larger lumen where it reaches the bony portion. The osseous part is narrower than the cartilaginous

and the narrowest part of the canal is at the junction of the middle and inner thirds.

The cartilaginous portion of the meatus has a partial framework of elastic fibro-cartilage, continuous with the pinna. This cartilage forms but  $\frac{2}{3}$  of the circumference, is incomplete above and behind and tails off as it passes inward to become attached to the lower third of the margin of the osseous meatus. This attachment is by dense fibro-elastic tissue which allows of the shifting of position of the pinna on traction. The cartilage presents clefts or fissures (*fissures of Santorini*) on the floor of the meatus, which are filled with fibrous tissue. They permit of easier movement of the cartilaginous meatus and allow the spread of inflammation or an abscess from the parotid gland below into the external meatus or *vice versa*.

The skin lining the outer part of the cartilaginous portion is supplied with numerous hairs, which help to keep out dust and insects, and with sebaceous glands which may be the starting point of small, circumscribed but very painful abscesses. The ceruminous or wax glands, resembling modified sweat glands, stud the skin covering the cartilaginous meatus, and their secretion, "ear wax," is thought to be a defense against dust and the intrusion of insects. When this wax is secreted excessively it may produce plugs which cover the drum membrane or block the meatus and so produce deafness which, curiously enough, usually comes on suddenly and is continuous. The skin lining the osseous portion is intimately blended with the periosteum and contains only a few wax glands. The skin of the meatus is liable to eczema and may become inflamed (otitis externa), giving rise to a profuse muco-purulent discharge. In addition to small, circumscribed, glandular abscesses a less common but more serious and more diffuse form may occur beneath the periosteum. This may spread out onto the surface of the mastoid, beneath the periosteum, or it may extend downward into the parotid region, through the fissures of the cartilage or a gap in the floor of the osseous portion. This gap is explained as follows. The osseous portion is largely formed by the outward growth of the tympanic ring, at first in two lateral tubercles which meet in the floor, leaving an opening mesial to their junction, which may sometimes persist. *Polypi* may grow from the soft linings of the canal and exostoses from its bony walls.

Foreign bodies are often lodged in the meatus and may be very difficult of extraction. More damage has been done in many cases by blind or forcible attempts to remove the foreign body than by leaving it in place. The ear drum and tympanum have been injured in such attempts at removal, while on the other hand, cases are reported where foreign bodies have remained in the ear from thirty to sixty years without harm. The extraction should only be attempted by means of appropriate forceps or a blunt hook, while the body is seen and the instruments guided to it through a speculum; or by means of a stream of tepid water forcibly injected through the narrow nozzle of a syringe so as to get behind the body and force it out.

The relations of the external auditory meatus, especially its bony portion, are of practical importance. The superior wall is in relation with the *middle fossa of the skull* and is separated from it by a bony plate 4–5 mm. thick, and sometimes thinner. Hence long-continued subperiosteal inflammation or bone disease in the meatus may extend to the meninges or the brain, without necessarily first involving the tympanum. Posteriorly the meatus is in relation with the *mastoid process* and, at its inner end, with the *mastoid antrum*. From the latter the meatus is separated by a thin plate of bone, sometimes defective, so that inflammations of the one may extend to the other and inflammation in the antrum may often cause a swelling or bulging of the postero-superior aspect of the inner end of the meatus. The inferior wall is in relation with the portion of the *parotid gland* occupying the back of the glenoid fossa and, as stated above, a congenital gap may occur here which permits the ready extension of inflammation from the one to the other. The anterior wall is in relation to the *temporo-maxillary joint* and may be fractured by the condyle of the jaw in falls upon the chin. As a result of this injury there may be considerable bleeding from the ear, as also in case the drum membrane is ruptured, hence this symptom does not necessarily indicate fracture of the base of the skull. The proximity of this part to the joint helps to explain the pain of movement of the jaw when the meatus is inflamed, but this is also explained by the two parts being supplied by the same nerve (auriculo-temporal).

**Nerve Supply.**—The *auriculo-temporal* supplies parts of the meatus and the outer surface of the pinna. The *great auricular* and *small occipital* also supply the pinna, while *Arnold's nerve* supplies the back of the concha and the lower and back part of the outer portion of the canal. Arnold's nerve, a small branch of the vagus, has been nicknamed "*alderman's nerve*" from the following circumstance: It is said that diners after a heavy dinner were wont to touch the back of the ear with a napkin moistened with rose water. This is said to be very refreshing by reason of the stimulation of Arnold's nerve and thereby, reflexly, of the main branch of the vagus, which supplies the stomach.

The *irritation of the meatus* by a plug of wax, the introduction of a speculum, the presence of a foreign body or of an inflammation may give rise to symptoms which are explained as *reflexes*. Thus *ear-coughing* and *ear-sneezing* are reflexes, through Arnold's nerve, of the branches of the vagus supplying the lungs. *Vomiting* has been caused in like manner by an irritation through Arnold's nerve of the gastric branches of the vagus. In *ear-yawning* the irritation is conveyed through the auriculo-temporal nerve to other branches of the fifth nerve which supply the muscles of the jaw. Again, other branches of the same division of the fifth nerve supply the lower teeth (inferior dental) and the tongue (gustatory); a circumstance that may account for the frequent association of earache with *toothache* or disease in the anterior two-thirds of the tongue.

The *tympanic membrane* is placed so as to face obliquely outward, downward and slightly forward. The *obliquity* with the horizontal plane is 30°–50° at birth and 40°–45° in the adult. According to

Fick the more vertical the membrane the more sensitive is it to sound and it has been observed to be less oblique in musicians than in those lacking in a taste for music. Owing to the inclination of the membrane and the sloping downward of the inner end of the canal an acute-angled sinus is formed between the two where small foreign bodies, pus and other fluids are likely to collect. The membrane is *nearly circular* but slightly longer vertically (10 mm.) than horizontally (9 mm.). Its *shape* however is somewhat irregular for above and anteriorly, where the tympanic ring is interrupted by a slight recess, the notch of Rivini, the membrane extends to the margin of the tympanum. This portion of the membrane, limited below by two small fibrous bands connecting the two angles or corners of the notch of Rivini with the short process of the malleus, bulges outward instead of inward and is thin and lax, hence called by Shrapnell *membrana flaccida*, and is known as *Shrapnell's membrane*. This from its thinness may be readily ruptured by a blow and through it pus may escape from the middle ear without perforating the membrane proper.

The *inward bulging* of the tympanic membrane is due to the position of the long process or *handle of the malleus* which is embedded between the circular and radiating fibers of the membrane. The center or *umbo* of this depression is slightly below the center of the membrane and, as may be seen from either side, corresponds to the slightly flattened end of the handle of the malleus. A section of the membrane below the umbo shows this part to be slightly convex externally. When pathological products such as mucus, pus, etc., are pent up in the tympanum the inward bulging is diminished or even replaced by an outward one. On the other hand, when the Eustachian tube is occluded and no air can reach the tympanum the atmospheric pressure on the outside of the membrane increases the inward bulging to such an extent that the stapes is constantly pressed inwards and a ringing in the ear is produced.

Otoscopic image of right ear drum. (TESTUT.)

The otoscopic image of the membrane as seen through an ear speculum is that of a round or oval, concave surface, pearl gray in color with

sometimes a violet or yellowish brown tinge and with the following markings. Extending from a little in front of the upper pole downward and a little backward to the umbo is seen the *handle of the malleus*. At the upper end of this, and near the circumference of the membrane, is a whitish point, the *short process of the malleus*. Behind and parallel with the handle of the malleus, but less distinct and not as long, is seen the *long process of the incus*. Extending downward and forward from the umbo is the "light cone," a whitish cone-shaped area of varying shape and size where the light thrown in is reflected back, owing to the inclination and curvature of the membrane. Pathologically this light cone may be wanting when a perforation occupies its position, when it is bulged outward or the surface dulled by an inflammation of the membrane. Sometimes the *chorda tympani* nerve may be seen crossing transversely near the upper end of the handle of the malleus. The *promontory* may also be seen behind the umbo.

Practically we may divide the membrane into the parts above and below the umbo. The section *above the umbo* corresponds to the ossicles, their muscles and ligaments, the *chorda tympani*, the *foramen ovale* and the *promontory*. The greatest *vascularity* is in this part, the blood vessels being especially prominent on each side of the handle of the malleus. The section of the membrane *below the umbo* corresponds to no important parts and is less vascular and less sensitive than the upper segment; hence *paracentesis* is usually practiced here and for the additional reason that the lower incision affords the better drainage of the tympanum. It is noticeable however that the floor of the tympanum is at a lower level than the lower end of the membrane so that perfect drainage cannot be secured in the upright position. As the membrane consists of a framework of circular and radiating fibers of connective tissue, covered internally by mucous membrane and externally by epidermis, it possesses *little elasticity*; hence incisions do not gape much and heal readily, often before it is desired, so that paracentesis may need to be repeated. In case of spontaneous perforation from ulceration the wider opening resulting may heal slowly and sometimes not at all. But an opening in the membrane does not necessarily produce much deafness.

The arteries supplying the membrane are derived from the stylo-mastoid and the tympanic branch of the internal maxillary, the latter supplying mostly the part below the umbo, the former that above it. The *auriculo-temporal nerve* supplies the membrane.

The **tympanum or middle ear** is a narrow cleft-like cavity intervening between the external meatus and the internal ear. It is separated from the former by the ear drum, the vibrations of which are transmitted to the internal ear by a chain of three *ossicles* which cross this narrow space. It contains *air* which reaches it from the pharynx through the Eustachian tube and it connects posteriorly with the mastoid antrum and cells. Its *mucosa* is ciliated except where it covers the membrane, the ossicles and the promontory, where it is thin and squamous. It measures 15 mm. in *height* and *length*, above it is 5-6

mm. *broad*, below 4 mm., and the umbo and promontory are only separated by 1–2 mm. It projects above the upper limit of the membrane where it widens out somewhat and is called the *tympanic attic*. The cavity lies obliquely so that its outer and inner walls look outward, downward and forward.

On its inner wall, opposite the umbo, is the *promontory*, above this the *fenestra ovalis* and below and behind the latter the *fenestra rotunda*. The *fenestra ovalis* leads into the vestibule and is closed during life by the stapes. In the angle between the roof and the inner wall, and appearing as a slight convexity above the *fenestra ovalis*, is the *facial canal* (*aqueductus Fallopii*) transmitting the facial nerve. The wall of this canal is very thin, especially in infants in whom it may be defective. This fact accounts for *facial paralysis* in the course of chronic otitis media, especially in children.

The *floor* of the tympanum is like a narrow gutter below the level of the ear drum and hence drainage of the tympanum is not perfect after paracentesis of this membrane. The floor is only separated from the *jugular and carotid fossæ* by a thin plate of bone and fatal hemorrhage from the carotid has followed necrosis of this bony plate.

The *outer wall* consists chiefly of the *membrane*, but is partly osseous and presents the apertures of entrance and exit of the *chorda tympani nerve* which lies beneath the mucous membrane of this wall. This nerve crosses the upper part of the membrane internal to the handle of the malleus. If affected in connection with otitis media its irritation causes prickling of the end of the tongue, its destruction unilateral loss of taste in the anterior two-thirds of the tongue.

The *roof or tegmen tympani* is a very thin layer of bone which separates the tympanum from the *middle fossa of the skull*. Defects are sometimes found in the tegmen so that in cases of otitis media inflammation may spread from the ear to the meninges or the brain by extension directly through such defects or after necrosis of the thin bony plate, or indirectly along small veins passing through the tegmen to the sigmoid and superior petrosal sinuses.

The *petro-squamous suture* forms the outer boundary of the tegmen, the *eminentia arcuata* over the superior semicircular canal and the groove leading to the *hiatus Fallopii* form the inner boundary. The suture is generally obliterated by the end of the twelfth year, before which time inflammation may readily spread through the suture membrane from the tympanum to the meninges. The suture not infrequently remains open longer. Fracture of the *tegmen* and rupture of its closely adhering membranes causes an escape of cerebro-spinal fluid into the middle ear. The tegmen is continuous with the roof of the antrum behind and slopes downward in front to become continuous with the roof of the Eustachian canal.

The *posterior wall* at its upper end, on a level with the *tympanic attic*, presents the irregularly triangular opening into the *antrum*, and below this there are sometimes smaller openings directly into the *mastoid cells*.

As the result of chronic inflammatory changes the *joints of the ossicles* may become *stiffened* so that they do not readily transmit slight vibrations. It is in such cases of partial deafness that the hearing is better in a noisy place, like a crowded street or a railway train, for the resulting vibrations are sufficient to set the ossicles in vibration and the additional vibrations, due to the voice, are more readily transmitted to the internal ear. When the malleus and incus are removed and the membrane is freely perforated a considerable degree of hearing may be retained, the vibrations being transmitted directly to the stapes through the aperture in the membrane. The tympanum communicates with surrounding parts by many apertures, both large and small, through which pathological processes may extend in various directions.

The **mastoid antrum**, variable in size but about as large as a pea, lies behind the attic of the tympanum into which it opens. The *passageway* is frequently on a higher level than the floor of the antrum, so that drainage into the tympanum from the antrum is not well provided for and fluid is apt to gravitate into the mastoid cells which communicate with it. As the *facial canal* descends on the *inner wall* of this passageway one must keep to the outer wall of the passage in operations, in order to avoid the nerve. It follows also that the antrum lies behind the facial nerve.

The *antrum* lies nearer the outer surface of the skull than the tympanum and is covered externally by the *descending plate* of the *squamous bone*, between the temporal ridge and the masto-squamous suture. This plate may present defects at birth, exposing the antrum. The *masto-squamous suture*, which is wide in infancy, persists frequently till puberty, occasionally through life, and traces of it are also found in the adult in the shape of foramina, etc., through some of which minute veins pass from the antrum and tympanum. Inflammation travelling along these veins may set up a periostitis on the mastoid. As long as this suture remains unossified inflammation may spread and pus find a free outlet to the surface from the tympanum and antrum, an occurrence not infrequent in children.

Operations confined to this plate of the squamosal, *i. e.*, above the masto-squamous suture, are safe as regards injury to the sigmoid sinus or the facial canal. Roughly speaking the *level of the antrum* corresponds to that of the upper half of the external osseous meatus and the passage between the tympanum and the antrum corresponds to the postero-superior quadrant of the meatus. Hence the **operation of opening the antrum** is commenced in the bone just behind this quadrant, where Macewen has pointed out the existence of what he calls the **suprameatal triangle**. This occurs in 99.5 per cent. and is well marked in 94.6 per cent. of cases. It is usually a depressed area, sometimes a slightly prominent one. It is bounded above by the posterior root of the zygoma, below by the postero-superior quadrant of the external meatus and behind by a line drawn vertically from the posterior border of the meatus. The **opening** is to be made at the latter line, the base of the triangle, and is to be carried inward, with a

slight inclination forward, parallel with the bony external auditory canal, the direction of which may be determined by a probe passed into it posteriorly between the skin and the bony wall. At this point of entrance the *outer wall* of the antrum is about 2 mm. thick in the infant, 1 cm. at nine years (Symington) and  $1\frac{1}{2}$  cm. ( $\frac{3}{5}$  inch) or less in the adult, while the *inner wall* averages  $\frac{3}{4}$  of an inch from the surface in the adult. Hence in infants pus in the antrum can readily reach the surface or be readily evacuated by operation. As the increase of growth of the mastoid involves principally the outer part the antrum becomes more and more deeply placed.

FIG. 13.

Coronal section of the right temporal bone, passing through the Eustachian tube and the middle of the tympanum. Both surfaces of the section are shown, the parts being hinged on the line *xx*. (GERRISH after TESTUT.)

The other relations of the antrum are of great importance in case of inflammation extending into this cavity or of operations to evacuate the pus. Such inflammations readily extend into the antrum from the tympanum on account of the free opening between them and the continuity of their lining mucosa. The *mucosa* of the antrum is thin and not ciliated. The *roof* or *tegmen antri* is a very *thin plate* (about 1 mm.) of bone continuous with but at a little higher level than the *tegmen tympani*. Inflammation may readily extend through this thin roof to the meninges, causing meningitis, or into the neighboring brain, causing an abscess of the temporo-sphenoidal lobe or of the cerebellum. The lower border of the posterior root of the zygoma indicates the *level of the roof* of the antrum and a few lines above this is the base

of the brain. That part of the anterior antral wall separating the antrum from the inner end of the external auditory canal is thin and sometimes defective so that pus from the antrum has been known to escape directly into the meatus and inflammation of the antrum may be shown by a bulging of the postero-superior aspect of this part of the canal. Postero-internally the antrum is in close relation with the *sigmoid sinus*, 5-7 mm. intervening in the infant. The rear of the antrum may be freely and safely exposed as far as its outer covering by the descending plate of the squamous extends.

**Development.**—The *antrum* is present and nearly of full size at birth while the *mastoid cells* are developed later. The *mastoid process* is present at birth but does not become pronounced externally until about the second year and it continues to grow for many years. The *mastoid cells* are developed with the process but at first are like spaces of cancellous bone; the true air cells do not appear until after puberty. The cells of the mastoid continue to enlarge and extend well into adult life, when they may reach superiorly within half an inch of the *squamo-parietal suture*, anteriorly over the external meatus, posteriorly to the *masto-occipital suture*, and rarely beyond it.

The antrum is surrounded by *mastoid cells* on all sides but its roof. Most of the mastoid cells open directly or indirectly into the antrum and are lined by a mucosa continuous with and similar to that of the antrum, hence in inflammation of the latter the former are secondarily involved. *Suppurative inflammation* of the mastoid antrum and cells is one of the most important complications of middle ear disease. Some of the more distant inferior cells are diploic spaces filled with red marrow, and have no direct connection with those above, but in case of inflammation the thin septa between may become disintegrated.<sup>1</sup> Internally the mastoid cells come in very close relation to the *sigmoid groove*. Only a thin osseous layer separates them and occasionally this is defective. As this layer is perforated, opposite the sigmoid bend, by minute veins leading from the mastoid antrum and cells to the sigmoid sinus thrombosis of the latter may result from inflammation in the former. In cases where the outer surface of the mastoid is perforated, as the result of a fracture, or a congenital, atrophic, or pathological loss of substance, emphysema may occur and form a tumor-like bulging (*pneumatocele*) over the mastoid, the air coming from the mastoid cells.

**The Eustachian tube**, connecting the tympanum with the nasopharynx, measures  $1\frac{2}{5}$  inches in length in the adult, and half of this in the infant, in whom it is also wider. Its direction is forward with an inclination of  $45^{\circ}$  inward and  $40''$  downward in the adult, while in the infant its downward inclination is only  $10^{\circ}$ . These facts explain the readiness with which inflammation spreads from the pharynx to the middle ear and pus or injected fluid in the middle ear escapes

<sup>1</sup> According to Zuckerkandl the mastoid cells are entirely air cells in 36.8 per cent., entirely diploic in 20 per cent., and partly air partly diploic cells in 42.2 per cent. of all cases.

into the pharynx. As the tube is shorter, wider and more horizontal in *infants* and young children inflammation spreads more easily from the pharynx to the tympanum in young subjects. The *tympanic orifice* of the tube is on a level with the roof and inner wall of the tympanum and, as it is on a higher level than the floor, it does not serve well for drainage. A straight instrument passed through the tube and on through the tympanum would strike the joint between the incus and stapes and pass into the antrum.

In the adult the posterior *one-fourth* of tube is *bony*, the rest is cartilaginous, the point of junction, in the petro-squamous angle, being the narrowest part of the tube. At the same point the tube bends slightly, though for practical purposes it may be regarded as straight. In the middle of its course it lies close to and parallel with the carotid artery, which is internal to it. The *lumen* of the bony portion is always open, that of the cartilaginous part is merely potential and is only open during the act of swallowing when air may pass from the pharynx to the tympanum and equalize the atmospheric pressure on the two sides of the membrane. When the tube is *obstructed*, as by inflammation or a thickening of the mucosa or by pressure upon its pharyngeal orifice, the pressure on the outside of the membrane is in excess, so that the latter is thrust inward and presses the stapes against the fluid of the vestibule which causes an annoying buzzing or singing. If the obstruction is but slight the singing may cease after an act of swallowing, or, failing in this, by a forcible expiration while the nose and mouth are kept closed (*Valsalva's method*) or by forcibly inflating the nose and naso-pharynx by a rubber bag whose outlet is held in one nostril while the patient swallows a mouthful of water as the bag is compressed (*Politzer's method*) or, finally, by inflation through a *Eustachian catheter* passed into the pharyngeal orifice of the tube.

These phenomena are readily explained by the *anatomical structure* of the cartilaginous part of the tube which is made of a plate of cartilage folded on itself, the two borders of which are joined by fibrous tissue on the outer aspect of the tube to complete the lumen. To this fibrous portion are attached the tensor palati and palato-pharyngeus, so that when they act in raising the palate or in deglutition the tube is opened by their pulling the fibrous portion away from the cartilaginous portion. So in swallowing or any act involving the elevation of the palate the Eustachian tube is opened. Advantage is taken of this by artillerymen, who hold open and breathe through the mouth when a loud report is expected. When we breathe through the open mouth the palate is kept elevated and consequently the Eustachian tube is kept open so that the vibrations of the air on the membrane may be equalized by reaching it from both sides. Thus not only the painful shock of the loud report is avoided, but even the danger of rupturing the membrane.

The trumpet-shaped **pharyngeal orifice**, the largest part of the tube, is vertically elongated and is marked by a prominent ridge above, in

front and behind. Its position is about at the *center* of the lateral aspect of the *naso-pharynx*, its upper border being about equidistant and half an inch from the roof of the pharynx above, its back wall behind, the level of the palate below and the end of the inferior turbinate bone in front (Tillaux). It lies nearly directly above the posterior margin of the aponeurosis of the soft palate and looks downward, inward and forward. At birth it is at or below the level of the palate.

With a knowledge of its position, and remembering that it is bounded above and at the sides by a projecting cartilaginous rim and is open below, we pass a **Eustachian catheter** in one of several ways: (1) After passing it through the inferior meatus of the nose with its beak downward until it touches the posterior wall of the naso-pharynx the beak is turned outward and the catheter is slowly withdrawn until it is felt to glide over the projecting posterior rim of the opening when it is turned still farther until the beak, and the ring on the handle, point to the outer canthus of the eye. (2) After reaching the posterior wall of the naso-pharynx the beak is turned inward and the catheter withdrawn until its beak catches on the posterior border of the nasal septum when the catheter is rotated through a semicircle so that the beak gliding over the upper surface of the soft palate enters the Eustachian orifice on its lower or open side. The curve of the catheter is such that when the curved portion catches on the septum the tip will be far enough behind the margin of the hard palate to enter the Eustachian orifice. We may also withdraw the catheter with its beak down until the latter catches on the posterior margin of the hard palate and then rotate outward through 90°, but this plan is not so sure on account of the difficulty of distinguishing between the posterior margins of the hard palate and of the aponeurosis of the soft palate.

Just behind the prominence caused by the pharyngeal orifice is a depression in the wall of the pharynx, the **fossa of Rosenmüller**. This may be mistaken for the opening of the tube, for it may readily engage the tip of the catheter, and it is the principal cause of error in passing the catheter. When the catheter is in Rosenmüller's fossa, the patient gives a sudden start when air is forced through it, but when the catheter is in the Eustachian tube the surgeon can hear the entrance of air into the ear by means of a tube passing between the patient's meatus and his own. This fossa is greatly deepened when the pharyngeal (Luschka's) tonsil, internal to it, is enlarged.

In cases of *deafness* associated with *hypertrophy of the tonsil*, which lies below the soft palate, the pressure of the enlarged tonsil itself may possibly be the cause of the obstruction of the tube, but the latter is more often due to the associated hypertrophy of the neighboring adenoid tissue and of that in the mucosa of the tube near the orifice. The movement of the *cilia* of the epithelium which lines the tube is toward the pharynx. The **lymphatics** of the external and middle ear and of the Eustachian tube enter glands near the angle of the jaw.

## THE FACE.

### Region of the Orbit and Eye.

The eyebrows are composed of layers similar to those of the scalp except that the subcutaneous layer contains but little fat and the muscular layer includes three intersecting muscles, the corrugator supercilii, the occipito-frontalis and the orbicularis palpebrarum muscles. *Incisions* made here should be parallel to the long axis of the eyebrow so that the cicatrix may be hidden in the hairs. Blows or falls may produce a *wound* made by the supraorbital margin cutting through from within and often appearing like an incised wound. The eyebrows, especially their inner end or head, correspond to the *frontal sinuses*. The outer end or tail of the eyebrows, at the level of the external angular process, is a favorite situation for *dermoid cysts*, which are here due to a portion of skin being shut in below the surface in the closure of the outer end of the orbito-nasal fissure. Such cysts are beneath and do not involve the skin and often indent the bone. The hairs of the eyebrows help to shade the eyes, to protect them from dust and to deflect the perspiration of the forehead beyond their limits. The corrugator muscle is supplied by the *facial nerve* and is affected in facial paralysis. The *lymphatics* of the outer half run to the parotid nodes, those of the inner end to the submaxillary nodes.

The eyelids (Fig. 14) serve to cover, protect and keep moist the eyes. Examining the component layers successively we find that (1) the **skin** is very thin and delicate so that extravasation of blood beneath it shows through as a "*black eye*" almost at once. It presents numerous transverse *folds* in line with which all *incisions* in the lid should be made. These folds are most marked beyond the tarsal cartilages and in the upper lid one deeper than the rest (*superior palpebral fold*), divides the lid into two parts, a lower smoother tarsal portion covering the globe, and an upper more wrinkled orbital portion covering the soft parts of the orbit. The folds of skin are due to its laxity and its loose attachment to the muscular layer by (2) a thin layer of **fatless connective tissue**. The *laxity of the skin* makes it well adapted for *plastic operations*. By reason of its loose attachment it is readily affected by the traction of cicatrices below the lower lid which draw the latter away from the globe and thus produce *ectropion* or eversion of the lid. *Epithelioma* frequently attacks the lids and may in time produce ectropion. The skin contains some *pigment* which helps to protect the eye from bright light, and the yellowish plaques sometimes seen in the skin in old people, especially near the inner canthus, are due to an accumulation of sebaceous matter in the numerous sebaceous glands.

3. The **orbicularis palpebrarum**, or sphincter muscle of the lids, by its *action*, closes the lids, raising the lower and depressing the upper one. As it is attached internally to the firm *tendo oculi* its contraction draws inward the outer commissure which is attached externally by the less firm external tarsal ligament. This inward motion of the

eyelids helps to wash the lachrymal secretion towards the inner canthus and the puncta lachrymalia. The contracture of the muscle (*blepharospasm*) closes the lids continuously and may reach such a degree as to invert the free border of the lids (*entropion*), the pressure of which may occasion ulceration of the cornea. The muscle is supplied by the *facial nerve* in paralysis of which the ability to wink or close the eyelids is lost.

FIG. 14.

Upper lid in sagittal section. (After MERKEL.)

4. Separating the muscle from the tarsi is a thin, loose connective tissue layer. This is readily infiltrated by oedema, inflammatory or bloody exudation, etc., which cause a rapid and considerable swelling of the lids. In the puffiness of the lids so common in Bright's disease and some other conditions the swelling is largely in this layer. This layer also includes fibers from the fibrous expansion of the levator palpebrae muscle in the upper lid and of the corresponding rectus muscle in both lids.

5. The stiff plates of closely felted connective tissue called the "tarsal cartilages" form the framework of those parts of the lids which cover the globe. The opposing *margins* are free, except internally and externally where they unite to form the *canthi*, the other margins are connected with the periosteum at the margin of the orbit by the *palpebral fascia*. The latter covers the soft parts of the orbit and is firm enough to prevent an extravasation within the orbit from reaching the surface of the eyelids. The *breadth* of the upper tarsns (10 mm.) is about double that of the lower and opposes the examination of the inner surface of the upper lid while the inner surface of the lower lid is readily exposed by drawing down that lid. To *expose* the inner surface of the *upper lid*, as in the search for foreign bodies, we direct the patient to look down and then seize the eyelashes and the edge of the lid and evert it by raising up the free border while the upper end of the lid is pressed down by a match, small pencil, etc. Attached to the upper border of the upper tarsus and the anterior surface just below this point is the *levator muscle* which raises this lid. As it is supplied by the *third nerve* this lid droops (*ptosis*), when that nerve is paralyzed. Incisions to reach the cavity of the orbit are made beyond the limits of the tarsi; through the palpebral fascia, usually that of the upper lid. The two tarsi, where they join internally and externally, are connected with the inner and outer orbital margins by the *palpebral ligaments*. Of these the inner, *tendo oculi*, is attached by two limbs to the two ridges bounding the lachrymal groove and thus embraces the lachrymal sac to which it is an important guide. It lies in front and external to the *lachrymal sac* at the junction of its middle and upper thirds and can be made prominent by drawing the lids outwards.

6. The *conjunctival mucous membrane* adheres closely to the back of the tarsi (*palpebral conjunctiva*). This part of it is thick, red and vascular and its degree of redness, in the absence of inflammation, is taken as an indication of the presence or absence of anaemia. In *granular lids* the little elevations known as granulations are due to enlarged nodules of adenoid tissue, mucous follicles and papillæ. From the contraction of the new connective tissue found abundantly in the membrane in such conditions the edge of the lids may be inverted (*entropion*). The rich sensory *nerve supply*, from the ophthalmic division and the infraorbital branch of the fifth nerve, explains the exquisite *pain* caused by conjunctivitis or the presence of a foreign body.<sup>1</sup>

The conjunctiva is reflected from the back of the lids onto the surface of the globe, the anterior third of which it covers.

The point of this reflection is called the *fornix*. The *upper fornix* is the deeper, extending above the corresponding tarsus to the junction of the inferior three-fourths with the superior fourth of the upper lid. Hence *incisions* to reach the orbital contents are made in the upper fourth of the lid so as to avoid the conjunctiva. The *external canthus*

<sup>1</sup> After the operation of removal of the *Gasserian ganglion* the loss of sensation of the conjunctiva renders the presence of the dust and foreign bodies painless, but at the same time the latter set up an inflammation of the conjunctiva so that the eye has to be kept closed and protected.

is several millimeters from the outer margin of the orbit and the conjunctiva extends beneath the lids here as an *external cul de sac* or *fornix*. It is in one of the cul de sacs, superior, external or inferior, that *foreign bodies* are likely to be lodged. To discover and remove such bodies the inferior and external fornices can be readily explored by drawing the lids downward or outward respectively, while the upper fornix may be explored by evertting the lid as described above, or the foreign body may often be removed by pulling down the upper lid so that its inner surface is wiped off on the outer surface of the lower lid. At the *inner canthus*, which reaches to the inner margin of the orbit, is an island of modified skin, the *caruncle*, and external to this the conjunctiva presents a small vertical *semilunar fold*, the homologue of the third eyelid or *membrana nictitans* of birds.

The conjunctiva covering the fornices and globe (*ocular conjunctiva*) is *thin* and loosely attached so that it is freely *movable*, which is of great value in some operations. Some of the *vessels* seen through the ocular conjunctiva belong to the underlying sclerotic, as can be shown by their remaining stationary when the conjunctiva is moved over them. This part of the conjunctiva has but little *vascularity*, unless it is inflamed, so that the white color of the sclerotic shows through it. The *looseness* of the *subconjunctival tissue* over the globe favors the development of *œdema*, which may reach such an extreme degree that the eye cannot be closed, and the cornea is partly or entirely covered. It also favors the occurrence of subconjunctival ecchymoses which may be due to the giving way of one of the poorly supported vessels, as in severe vomiting or a paroxysm of whooping cough, or to an extravasation from a fracture of the base of the skull involving the orbital roof. One peculiar feature of subconjunctival ecchymoses is the fact that they retain their scarlet color, owing to the thinness of the conjunctiva which allows the air to reach the blood and keep it oxygenated. Although the conjunctiva is normally very thin it may hypertrophy in the form of a vascular triangle (*pterygium*) the base of which is directed toward one of the canthi, the apex to and finally over the pupil.

The arteries of the eyelids, derived from the lachrymal and palpebral branches of the ophthalmic, form arches near the borders of the tarsus in the connective tissue layer beneath the muscle. The veins enter into branches of the ophthalmic at the outer canthus and into the veins of the face at the inner canthus. Thus the veins of the eyelid and through them those of the face communicate with the cavernous sinus through the ophthalmic vein, so that an infection of the eyelid or face is capable of causing septic thrombosis of the cavernous sinus.

The *free border* of the eyelids, averaging 30 mm. in *length*, consists of a *ciliary portion* (outer five-sixths) and a *lachrymal portion* (inner one-sixth) separated by the projecting *papilla* on which is the *punctum*. The *ciliary portion* is flattened and 2 mm. thick. The two or three rows of obliquely implanted *hairs* which it presents anteriorly may occasionally project internally and irritate the conjunctiva and cornea.

PLATE II.

FIG. 15.

Horizontal section of lachrymal sac passing through the tendo oculi. Diagrammatic. (Testut.)

This may be due to a vicious implantation (*trichiasis*) or to a general inversion of the border (*entropion*). Inflammation in the hair follicles, their sebaceous glands or the Meibomian glands, but especially in the sebaceous glands, constitutes a "stye." The secretion of the *Meibomian glands* lubricates the cornea and renders it waterproof. When this secretion is retained in one of the glands it gives rise to a "*tarsal tumor*." The border of the lid with its sluggish terminal circulation, its junction of skin and mucous membrane, its moist surface and numerous glands is frequently the seat of troublesome inflammation.

**The Lachrymal Apparatus.**—The lachrymal gland reaches to within a few millimeters of the anterior orbital margin at the upper and outer angle and lies between the superior and external recti. It is enclosed in a fibrous capsule derived from the orbital periosteum so that, according to Tillaux, it may be opened or removed, without opening the post-ocular space, by incising the periosteum at the margin of the orbit and stripping it off from the roof until we reach a point just above the gland. Cysts, tumors and abscesses may occur here. A lower accessory portion of the gland lies above the outer third of the upper conjunctival fornix where also the ducts of the gland open. From this point the tears, neutral in reaction, fall over the front of the eyeball, flushing it of dust, etc., and are swept inward to the puncta by the contractions of the orbicularis muscle.

Each *papilla* curves backward to the surface of the eye and presents at its summit the *punctum* or commencement of the *canaliculus* (Fig. 16). The position of the puncta in close apposition with the eye is well adapted for draining off the tears which collect here. Sometimes the puncta are displaced forward so that the tears collect and overflow (*epiphora*) onto the cheek. This may occur when the lower punctum only is displaced, as in swelling of the lid, entropion or *ectropion*. Among the causes of the latter is a relaxed condition of the orbicularis, present in old age or in facial paralysis when this muscle is paralyzed, for the puncta and inner margin of the lids are held in apposition with the surface of the globe by a specialized part of the orbicularis muscle, known as the *muscle of Horner* or the *tensor tarsi*. This muscle arises from the lachrymal bone behind the posterior or reflected limb of the *tendo oculi* and from the latter and is attached to the back of the inner end of the tarsi as far as the papillæ. By drawing inward and backward the outer end of the *tendo oculi* and thereby the tarsi, it may also compress the lachrymal sac. It may also help to open or keep open the canaliculi (Fig. 15).

The *lower punctum* is slightly external to and larger than the upper and both are held open by a firm fibrous ring. The *canaliculi* run at first vertically and then bend sharply and run nearly horizontally inward, a point to be remembered in passing a stylet or in injections. *Obstruction* of the puncta or canaliculi, due to inflammation or to compression by an inflammation, etc., external to them is another cause of the overflow of tears.

The lachrymal sac, lodged in the lachrymal groove just internal to the inner canthus, receives the canaliculi antero-externally and has the following landmarks. The inner ridge bounding the lachrymal groove is continuous with the inferior orbital margin and can be palpated. By drawing the eyelids externally the *tendo oculi* can be seen and felt crossing in front of the sac at the junction of the upper and middle thirds. Consequently it is below the tendon and external to the above ridge that we incise to open the antero-external aspect of the lachrymal sac in case of lachrymal tumor, to give vent to pus or to introduce instruments. A lachrymal abscess always points below the tendon. In introducing stylets, etc., it is important to know the course and direction of the lachrymal sac and its continuation, the

FIG. 16.

*nasal duct.* These together are not quite straight, but slightly curved so as to be concave posteriorly and are directed downward, backward and slightly outward. Together they average a little over one inch in length (26 mm.) of which the sac represents the upper two-fifths. *Lachrymal tumor* is usually due to a chronic inflammation and thickening of the lining mucous membrane. It forms a swelling at the inner corner of the orbit and its evacuation is occasionally followed by a lachrymal fistula. *Valves* occur, but are not constant, at the opening of the canaliculi into the sac and between the sac and the nasal duct. According to some the latter, which is the less constant valve, may be responsible for some cases of lachrymal tumor.

The lachrymal sac is enclosed by a fibrous sheath derived from the splitting of the periosteum at the ridges which bound its groove. The

tendo oculi is a thickening of this capsule. This sheath limits the distension of the sac which may reach 6 mm. antero-posteriorly and 4 mm. transversely. The **nasal duct**, lodged in the lachrymal canal, is about 3 mm. in *diameter* and its narrowest point is at the junction with the sac. It is the unobiterated part of the orbital fissure and opens by a vertical *slit-like opening* into the *inferior meatus* of the nose. It is difficult to find and enter this opening in the cadaver, hence catheterization from below in the living subject is too difficult to be advisable. This *lower opening* is situated about 3 cm. behind the free margin of the ala of the nose, 8-10 mm. behind the anterior end of the inferior turbinate bone, in the angle between the short, oblique, anterior limb and the longer and more horizontal posterior limb of this bone and in the angle between the lateral wall of the nose and the inferior turbinate bone.

All the ducts by which the tears are removed are *held open*, the puncta by the fibrous rings surrounding them, the canaliculi by the tensor tarsi muscle, the lachrymal sac by its fibrous sheath and the tendo oculi, the nasal duct by its bony walls. This circumstance favors the theory of Sédillot, which explains the *passage of tears* by the *vacuum* produced by the air passing across the lower opening of the duct on the principle of the mercury vacuum pump. It may also be said that the process of *winking*, due to the action of the orbicularis, keeps the puncta applied to the eye, holds open the canaliculi by means of the tensor tarsi and compresses the sac so as to force the tears downward, as the opening into the canaliculi is guarded by a valve. After such a compression the emptied sac exerts a suction to draw the tears into it. By means of these ducts the mucous membrane of the nose and eye are continuous and inflammation may spread from one to the other. Inflammation of the sac and duct is usually an extension from an inflammation of the nasal mucosa.

### The Orbit.

The antero-posterior **axis** of the pyramidal orbital cavity is directed obliquely forward and outward and measures  $1\frac{3}{4}$  inches. The **inner walls** though convex laterally are nearly parallel with one another, a fact, like that of the parallelism of the optic axis, which is peculiar to man. The inner wall, **floor** and **roof** are very thin. The inner wall separates the orbit from the ethmoid cells and nasal fossa, the floor from the maxillary antrum and the roof from the cranial cavity. *Foreign bodies*, such as foils, umbrellas, canes or sharp sticks, thrust into the orbit have readily *penetrated* through these thin walls into the ethmoidal cells, the nose, the antrum or the cranial cavity. These walls offer little resistance to *tumors* extending into the orbit from the surrounding cavities or vice versa. This is especially seen in tumors of the antrum which elevate the floor of the orbit, destroy the intervening bone, and displace forwards the orbital contents, causing *exophthalmos*.

The presence of the bony *groove* and *canal* for the *infraorbital nerve* in the floor of the orbit should be borne in mind, for the nerve is liable to be pressed upon by tumors of the orbit or antrum. There are various channels of *communication* between the orbit and the *surrounding cavities*. It communicates with the *cranial cavity* through the optic foramen and the sphenoidal fissure at the apex of the orbit, with the *nose* through the nasal duct and with the *zygomatic* and *sphenomaxillary fossae* through the sphenomaxillary fissure. Through this fissure blood may find its way into the orbit after violent blows on the temporal region.

At each angle between the orbital walls there is some point of interest. Thus at the *supero-internal angle* are the *ethmoidal canals* (and the pulley for the superior oblique); at the *infero-internal angle* the *lachrymal canal*; at the *infero-external angle* the *sphenomaxillary fissure* and at the *supero-external* the depression for the *lachrymal gland*. The anterior end of the *sphenomaxillary fissure*, through which we pass the flexible saw in removal of the upper jaw, is 15 mm. from the margin of the orbit. The *outer walls* are inclined to the sagittal plane at an angle of nearly  $45^{\circ}$ , hence the interior of the orbit is most conveniently reached by incisions external to the globe between it and the outer wall. The bones of the orbit are especially liable to develop "ivory" *exostoses*. The *largest part* of the orbit is not at its margin but about 1 cm. behind it.

The *orbital margin* is prominent and easily felt above, below and externally, more rounded and less readily palpable internally. The eye is well protected by this prominent rim. As the *base* of the orbit is *bevelled* so that the plane of its margin looks outward as well as forward the range of vision is notably increased laterally but at the same time the eye is more vulnerable from the outside. Mesially the eye is protected from injury mainly by the nose. On the *supraorbital margin* at the junction of the inner and middle thirds is the *supraorbital notch* or foramen through which the supraorbital nerves emerges from the orbit. The horizontal *diameter* of the orbital margin is about  $1\frac{1}{2}$  inches, its vertical diameter a little over  $1\frac{1}{4}$  inches; the similar diameters of the globe are respectively 24 and 23 mm.

**The Contents of the Orbit.**—These include the globe and its vessels, nerves and muscles embedded in a quantity of fat. (Fig. 17.) In addition there is an important aponeurotic capsule, supporting the globe and limiting the action of its muscles. This is the **capsule of Tenon** or **orbital aponeurosis** whose prolongations connect it with the muscle sheaths and the orbital periosteum. (Fig. 18.) The capsule of Tenon proper is that part of the fascia of the orbit which surrounds the posterior  $\frac{5}{6}$ , or the sclerotic portion of the globe. It extends forward as far as the cornea and is continued backward around the optic nerve, with whose sheath it fuses. In order therefore to reach the sclerotic, as in a tenotomy of the recti tendons for strabismus, we must cut through two layers, the ocular conjunctiva and Tenon's capsule. This capsule separates the globe from the fat, etc., in the posterior

# PLATE III.

half of the orbit; in fact with its prolongations it forms a kind of *septum* between the globe in front and the rest of the orbital contents behind. The *inner surface* of this capsule is loosely connected with the sclerotic by lax and delicate areolar tissue and is smoothly lined by endothelium. It is in fact the outer wall of a large lymph space and forms a species of *socket* in which the globe moves without friction.

In order to reach their insertions in the sclerotic coat of the globe the tendons of the ocular muscles must pass through this capsule. Where they do so, opposite the equator of the globe, the aponeurosis invests the *muscle tendons* in a *fibrous sheath* which is prolonged forward to their insertions and backward toward the middle of the orbit where it fuses with the proper sheaths of the muscles. A small serous bursa is formed on the anterior surface of each tendon. In consequence of this arrangement of the prolongations of the capsule the muscles do not retract to their limit after division of their tendons, close to their sclerotic insertion, but are held by the capsular prolongation. In this way, after tenotomy, the muscles retain a hold on the globe so that they still act on it through the capsule. Even after enucleation of the globe the muscles retain a hold on the capsule and so may furnish some motion to the stump and the artificial eye which occupies it. In addition *prolongations* pass from the aponeurotic sheaths of the recti to the *walls of the orbit* a little behind its margin, where they are continuous with the orbital periosteum. Of these prolongations or bands the *external and internal*, from the sheaths of the corresponding recti to the orbital walls behind the corresponding palpebral ligaments, are the best developed. They are known as the *check ligaments* for they check excessive outward and inward rotation of the globe. Together with that part of the capsule connecting them beneath the globe they have been called by Lockwood the *suspensory ligament*, as they suspend the globe as in a hammock. According to Lockwood it is important to preserve the attachments of this ligament in removing the maxilla in order to prevent the eyeball from sinking downward. The orbital band or *prolongation* from the *superior rectus* to the orbital walls connects the latter muscle with the *levator palpebræ* just above it. Hence the contraction of these muscles is not entirely independent and the *superior rectus* is to a slight extent an elevator of the upper lid so that elevation of the eye and of the lid are very intimately associated with one another.

The *attachment* of the recti *muscles* to the *orbital walls* by means of the prolongations from their aponeurotic sheaths has the following *practical consequences*. The muscles do not retract far when divided and they are held away from the globe by these prolongations, which act like pulleys, so that the muscles when they act do not compress the globe as they otherwise would. Furthermore on account of the obliquely forward direction of these prolongations the recti, when they act, do not retract the globe as much as they otherwise would and hence do not overpower the oblique muscles which act weakly as pro-

trusors. In this way the action of the recti is confined to the movements of the globe on its various axes.

The **periosteum** lining the orbit is continuous at the orbital margin with that of the surface of the face and cranium and at the sphenoidal fissure and the optic foramen with the periosteal layer of the dura.

The **muscles** of the orbit are *inserted* into the sclerotic about one fourth inch from the cornea, or, according to Fuchs, the internal rectus 5.5 mm., the inferior 6.5 mm., the external 6.9 mm., the superior 7.7 mm. from the corneal margin. The points of insertion form a spiral which, commencing with the internal rectus and ending with the superior, gradually reaches further from the edge of the cornea. The *tendons* of the internal and external recti are often *divided* for *strabismus* and are *reached* at the above distances from the corneal margin after *incising* the conjunctiva and the capsule of Tenon. The tendons are then hooked up with a blunt hook and divided close to their sclerotic attachment. In *enucleation* of the globe this is repeated with the four recti tendons after incising the conjunctiva and capsule of Tenon circularly a little outside of the margin of the cornea. The optic nerve is then divided by curved scissors from the outside of the globe. The latter may be enucleated without opening the posterior compartment of the orbit. The *width* of the thin flat tendons varies from 7 to 9 mm.

**Muscular Actions.**—If the antero-posterior axis of the orbit were in the same line as that of the eyeball the **superior and inferior recti** would simply elevate and depress the eye, for their line of action is in line with the axis of the orbit, but as their line of action forms an angle with the antero-posterior axis of the globe and passes internal to its vertical axis, both muscles adduct the eye. On the other hand both the **superior and inferior oblique** abduct the eye and the former depresses, the latter elevates it. Hence to produce simple elevation or depression of the eye the superior oblique acts with the inferior rectus and the inferior oblique with the superior rectus to counteract the adduction of the recti muscles. The **external and internal recti** produce simple abduction and adduction as their lines of action are parallel with the horizontal plane of the eye. *Abduction* is also produced by both oblique muscles acting together and adduction by the superior and inferior recti acting together. In case of weakness, paralysis or abnormal length of one muscle the opposing muscle overacts and turns the eye away from the weaker side and the eye cannot be moved to the full extent if at all in the opposite direction. **Strabismus**, squint or cross eye, is thus produced. If the patient tries to look in the direction of the affected muscle the affected eye fails to move, so that the eyes are directed in different directions and *double vision* results. Double vision does not result on looking toward the side to which the affected eye is kept directed. To avoid double vision the patient turns his head to the side toward which the affected muscle can not move the eye so that the muscle is not called upon to act. Thus if the right external rectus is paralyzed the right eye is directed internally and the patient has little difficulty in look-

ing toward the left, but if he tries to look toward the right the right eye fails to be abducted and remains stationary. Hence the head is kept constantly turned toward the right to allow him to look in this direction for he can move both eyes in the opposite direction.

**To Detect the Muscular Paralysis** by looking at the patient's face.—Ranney has given the rule that: "The head is so deflected that the chin is carried in a direction corresponding to the action of the affected muscles." One affected with strabismus is often able to educate himself to disregard one visual image; which would give rise to double vision, and to use the other eye as the "working eye." This is especially true in case of a double convergent squint.

The superior and inferior recti are supplied by the same nerve, the third, but the external is supplied by the sixth and the internal by the third nerve. Hence *strabismus* from weakness or paralysis of one of two opposing muscles is usually an *internal or external* one, as either the internal or external rectus is more likely to be affected without the other. There may be another reason why double *convergent strabismus* is a particularly common form. For in that congenital defect of the eye in which the rays are naturally focused behind the retina (*hypermetropia* or far-sightedness) the ciliary muscle struggles to accommodate the lens so as to properly focus the rays. This action of accommodation is closely associated with that of convergence or adduction, for the same nerve (third) supplies both muscles, so that a certain amount of the energy employed in accommodation passes into the internal recti and the child comes gradually to a convergent squint.

**Nerves of the Orbit.**—The fibers of the *optic nerves* decussate in the optic commissure so that the inner half of one eye may work in harmony with the outer half of the other, for the image of an object on one side of the main axis of vision is received on the opposite (inner and outer) but corresponding side (right or left) of both eyes. When therefore the *optic tract* of one side is *paralyzed* by pressure, etc., the outer half of the retina on that side and the inner half of the retina on the opposite side are blind, and objects on the opposite side from the lesion can not be seen (*hemianopsia*). The optic nerve has been severed by a stab wound of the orbit and torn across or pressed upon in fractures of the orbit or of the small wing of the sphenoid. The optic nerve is accompanied through the orbit by an investment of dura, arachnoid and pia, continued from the cranial cavity. These layers are not adherent together but leave a potential space between them as in the cranial cavity. In this respect the optic differs from the other cranial nerves from the third to the twelfth. Cases of sudden blindness without visible changes on ophthalmoscopic examination are to be explained by a hemorrhage or other effusion within this meningeal sheath. The capsule of Tenon is continuous with this sheath at the back of the globe. The optic nerve occupies the posterior half of the orbit.

**The third nerve** (*motor oculi*) *supplies* all the muscles of the orbit except the external rectus and the superior oblique and, through the

lenticular ganglion, it supplies the ciliary muscle and the sphincter fibers of the iris. Many of the *actions* of the third nerve are seen in viewing near objects. Thus both eyeballs are directed inward by the *internal recti* acting in unison, for which purpose the third nerves of the two sides are associated at their origin in the gray matter around the aqueduct of Sylvius. The *pupil* is also contracted by its sphincter fibers to cut off the peripheral rays and the *lens* is made more convex by the ciliary muscle to focus the divergent rays.

When the *third nerve* is completely *paralyzed* the upper eyelid droops (*ptosis*) from paralysis of the levator palpebrae, there is a *divergent squint* with double vision (*diplopia*) from the unopposed action of the external recti, the *pupil* is *dilated* and cannot be contracted on account of paralysis of the circular fibers of the iris and *accommodation* for near objects is *lost* from paralysis of the ciliary muscle. Rotation of the globe in a direction outward and downward is still possible by means of the superior oblique and the external rectus but otherwise the eye is motionless. The globe may *protrude* somewhat from the relaxation of three of the recti muscles. In partial paralysis these symptoms may be either partly developed or only one or two may be present. The *pupil* is *contracted* not only in viewing near objects but also under the influence of a bright light. The latter contraction is reflex, the former is a matter of accommodation. The pupil in which the reflex contraction is absent while the accommodation contraction is present, as in locomotor ataxia, is called the "*Argyll-Robertson pupil*."

In *paralysis* of the **fourth nerve**, which *supplies* the superior oblique only, there may be little change in the mobility of the globe for the function of this muscle may be performed vicariously, at least in part. But there will be diplopia in certain positions of the head, for there is deviation of the eye inward on lowering the object viewed. That the muscles of the two sides may act in unison the fibers of the two nerves decussate in the gray matter around the Sylvian aqueduct.

When the **sixth nerve** is *paralyzed* there is *convergent strabismus* with consequent *diplopia* owing to the paralysis of the external rectus, which alone it supplies, and the unopposed action of the internal rectus. As the patient is unable to rotate the eye directly outward the head is turned outward instead. The fibers of the two sixth nerves do not decussate at their origin as the two external recti do not need to act in concert. The nucleus of the sixth nerve is connected with that of the third nerve of the opposite side by fibers which pass eventually into the internal rectus so that both eyes can be directed to the right or left by the action of a single nucleus.

Paralysis of all the oculomotor nerves indicates a lesion which is probably at their central origin or at the cavernous sinus, in the wall of which they lie near together.

When the *ophthalmic division of the fifth nerve* is *paralyzed* there is *anaesthesia* of the globe, conjunctiva, upper eyelids and other parts supplied. Under these conditions the conjunctiva and cornea, espe-

cially the latter, are apt to be the seat of *ulceration*.<sup>1</sup> Hence after removal of the Gasserian ganglion for desperate trigeminal neuralgia the eye has to be carefully protected or altogether closed.

The **supraorbital branch** of this nerve, which supplies the scalp nearly as far back as the lambdoid suture, is not infrequently the seat of neuralgia. When it demands operative treatment it may be readily exposed by a horizontal *incision* centering at the junction of the middle and inner thirds of the supraorbital margin, where the notch if present can be felt. Continued pressure on the nerve at this point may be used to detect a person shamming insensibility or to rouse a person from alcoholic coma. No malingerer can bear the pressure for long.

The effects on the eye of a *paralysis* of the **sympathetic fibers**, which reach it along the internal carotid from the cervical sympathetic, are as follows. There is some drooping of the upper lid from a paralysis of the unstriped muscle fibers (superior palpebral muscle of Müller) which extend from the under surface of the levator palpebræ muscle to the upper margin of the tarsal cartilage. There is some recession of the globe which is explained by some as due to the paralysis of smooth muscle fibers bridging over the sphenomaxillary fissure, the *orbitalis muscle* of Müller. The *removal* of the cervical sympathetic ganglia, advised and practiced for the treatment of exophthalmic goitre, may therefore improve the exophthalmos in this way. The *pupil* is also narrowed and loses its power of dilatation by the paralysis of the radiating dilator fibers of the iris. The caliber of the blood vessels of the orbit has not been observed to change in paralysis of the cervical sympathetic.

Damage to the orbital nerves may be due to fractures of the orbit or the base of the skull, wounds of the orbit, and the pressure of tumors, aneurisms and bloody or inflammatory effusions along their course or at their origin. The sixth nerve is more liable to be injured in fractures of the base of the skull on account of its mere intimate connection with it.

**Vessels of the Orbit.**—The *arteries* are small and seldom give trouble when divided in enucleation of the globe for they can be readily compressed against the bony wall. The ethmoidal arteries may be torn in a fracture of the anterior cranial fossa. *Pulsating tumors* of the orbit may be due to a traumatic aneurism of an orbital artery, to an arterio-venous aneurism between the internal carotid artery and the cavernous sinus or to pressure upon the ophthalmic vein by an aneurism of the internal carotid. In these pulsating tumors the eye is also protruded. Pressure upon the *ophthalmic vein*, or the cavernous sinus into which it empties, by a tumor or an inflammatory deposit, etc., causes a venous congestion of the tributaries of the vein. This congestion is visible through the ophthalmoscope as a “choke disc.” The

<sup>1</sup>This is due partly to the paralysis of the trophic nerve fibers contained in the nerve; partly to the anesthesia which allows the parts to be readily injured as there is no sensation and the reflex winking, due to irritation of the conjunctiva, is wanting; and partly to the loss of the reflex of the sensory nerves upon the caliber of the blood vessels so that the progress of inflammation is unopposed.

presence of such a condition may assist in the diagnosis of a supposed tumor or deposit at the base of the brain. As the facial vein, through the angular, communicates freely with the ophthalmic and there are no valves in these veins the venous congestion in the latter vein may be relieved through the former, if the condition has come on slowly. This same free communication renders serious any septic condition of the face in the neighborhood of the facial vein (carbuncle, erysipelas, etc.), on account of the danger of the infection extending along the veins to the cavernous sinus and setting up a septic sinus thrombosis.

The amount of fat (Fig. 17) behind Tenon's capsule, which embeds the other structures of the orbit, is partly responsible for the varying prominence of the eyeball in different persons or the same person at different times. The absorption of this fat in cases of wasting disease or prolonged illness causes the sunken eye, characteristic of such conditions. This loose fat allows the ready spread of orbital abscess which may follow injuries or inflammations of the orbit, the globe or adjacent parts. The pus may occupy the entire posterior compartment of the orbit (*i. e.*, behind the capsule of Tenon) and displace the eyeball forward, limiting its movements. The pressure of the vessels interferes with the venous circulation and causes great redness on the conjunctiva and swelling of the lids. A similar effect may be produced by *emphysema* of this fatty tissue, which may result from fracture of the inner wall of the orbit involving the nasal fossa and which is increased in amount on blowing the nose. This fat also furnishes a favorable site for the growth of *tumors* and the lodgment of **foreign bodies**. Some of the latter are of remarkable size and shape and they sometimes remain for long periods of time without causing much trouble. For example, a case is described by Lawson where an iron hat peg three inches long lodged in the orbit for several days without the patient knowing it. In other cases suppuration takes place and nature gets rid of the foreign body through the opening or incision of the abscess. In a remarkable case of this kind described by Furneaux Jordan a man, several weeks after threshing wheat, ejected from a bed of pus, by pressure on the lower lid, a sprouting grain of wheat which had set up a severe ophthalmia.

### THE NOSE, NASAL FOSSÆ AND ACCESSORY SINUSES.

The **external nose** is largely for cosmetic purposes, a fact strikingly illustrated by the hideous appearance of those with marked nasal deformity. The *nasal cavities* serve the *functions* of olfaction, and respiration (filtering, warming and moistening the air) and assist in the taste and voice.

The *groove* between the nose and the cheek is a favorable site for *incisions*, as in excision of the maxilla, for the resulting scar is scarcely perceptible. From without inward we find the following *layers* composing the nose.

(1) **The skin** is thin and loosely adherent over the root and most of the dorsum of the nose, thick and closely bound to the subcutaneous tissue over the alæ. Hence in plastic operations the skin readily lends itself to the formation of flaps in the former situation but not in the latter. The skin is extremely *vascular* so that wounds and plastic operations heal well. This vascularity explains the readiness of the nose to assume a rosy color from the dilating effect on the vessels of heat, cold, alcohol, etc. The skin of the lower part of the nose is furthermore very richly supplied with *sudoriferous* and *sebaceous glands* so that it is a favorite site for acne. The hypertrophic form of acne known in this situation as "grog blossom" may produce a red tuberous enlargement of considerable size. From an experience of several cases I have found that this disfigurement may be satisfactorily treated by shaving down and shaping the nose, taking care not to cut through the mucous membrane, and then skin grafting the surface or allowing it to cicatrize. *Lupus*, *lupus erythematosus* and *epithelioma* are frequently met with here. The plastic operations, or the removal followed by skin grafting, for epithelioma give excellent results. Notwithstanding the abundant blood supply the nose, like the ear, is prone to *frost bite* on account of its exposed situation and the superficial position of the vessels, the circulation of which at the edge of the nostril is terminal. The vascularity of the lower part of the nose favors congestion, which partly accounts for the pain in inflammation here. For, on account of the firm adherence of the skin and subcutaneous tissue and the density of the latter tissue in this part of the nose, the swelling due to congestion necessitates pressure upon the nerves. These *nerves* are branches of the first or second divisions of the fifth nerve.

The next layer (2) the **subcutaneous tissue** has already been referred to. It is loose above, dense below. The subjacent or *fibromuscular layer* (3) requires no special notice. (4) The **osteocartilaginous layer** forms the framework of the nose. This is also supported by the osteocartilaginous *nasal septum*, the loss of substance of which, especially in its cartilaginous portion, may affect the shape of the nose.

The movability of the lower or cartilaginous part of the nose obviates many **fractures**. The latter are most common through the lower and thinnest third of the nasal bones. In the upper third fracture is rarest on account of the thickness and firm support of the bones, but it is here most serious, for it requires considerable force and is liable to involve the vertical and cribriform plates of the ethmoid and thus cause an indirect fracture of the base of the skull. The *displacement* of bony fragments in a fracture of the nose, which is due solely to the direction of the force, should be *reduced* by elevation from within the nasal cavity, as by the beak of a steel sound, combined with manipulation from without. Otherwise *deformity* results. *Union* of the fragments has been observed as early as the seventh day (Hamilton) and it occurs more rapidly than with any other fracture. When (5) the **mucosa** is torn through in a fracture, *epistaxis* and subcutaneous

emphysema are likely to occur and the latter is increased on blowing the nose. The bony portion or bridge of the nose is not infrequently much **depressed**. This depends not so often upon fracture as upon imperfect development from malnutrition in those with inherited syphilis. The cartilaginous part may also be destroyed by the ulceration of lupus, syphilis or epithelioma.

The various deformities of the nose, on account of the hideous disfigurement often produced, have led to numerous **plastic operations** (*rhinoplasty*). Some of these were practiced centuries ago. *Partial rhinoplasty* often gives excellent results. A *depressed bridge* of the nose may be improved by the introduction beneath the skin of an aseptic substance to fill out the depression. The difficulty in *total rhinoplasty* is that a nose made of soft parts has no firm support and is liable to contraction. For this reason the *Indian method*, by which the new nose is made of a flap from the forehead, has been modified to include in the flap the outer table of bone and the flap is not twisted as in the Indian method but inverted and its raw outer surface covered by skin flaps from the sides. In cases where there is an actual loss of the nose and not a mere deformity the operation is advisable.

The limits of the *cartilaginous part* should be remembered, for in introducing and opening a nasal speculum the latter should not be passed beyond those limits, otherwise pain results. The lower of the two pairs of *cartilages* of the nose are curved around in front of the nostril, whose contour they form. The mesial interval between their internal branches can be felt at the tip of the nose and into it projects the septal cartilage. The latter can therefore be reached and resected by a median incision between the lateral cartilages without opening the nasal cavities.

Several **operations** are performed on the nose to *expose the nasal fossæ* or even the *nasopharynx* behind. In *Rouge's operation* the incision is made through the mucous membrane where it is reflected from the gums to the upper lip, between the second bicuspid of both sides. Then the soft parts which connect the upper lip and nose to the bone are divided and the lip turned well up, exposing the anterior part of the nasal fossæ without any incision of the skin. Or the nose may be turned down after incising the soft parts in the groove on either side of it and across its root and dividing the bone in the same line.

The *suture* between the nasal and frontal bones at the root of the nose is a favorite place for *meningoceles*, etc. They have been mistaken for *nævi*, being often covered by a thin vascular skin. In rare instances they escape through the cribriform plate into the nasal fossæ, and being mistaken and treated for a polypus, the cribriform plate has been injured and fatal meningitis resulted.

The *nasal fossæ* open in front by the nostrils and communicate behind with the *nasopharynx* through the posterior nares. The *nostrils* or *anterior nares* look downward and are at a somewhat lower level than the floor of the nasal fossæ. Hence in *examining* the fossæ as through

PLATE IV.

FIG. 19.

Transverse vertical section of the nasal fossæ, viewed from in front, showing the back of the right orbit and the right antrum of Highmore, with the sphenomaxillary fossa behind the latter, exposed through an opening of its posterior wall. (Zuckerkandl.)

a speculum the tip of the nose is raised and the head is thrown back. In this manner the floor of the nose, the lower part of the septum, the greater part of the inferior turbinate bone and the lower margin of the middle turbinate bone may be seen, with a good light. The nostrils are separated by the *columna*, composed of skin and fibrous tissue, which extends below the septal cartilage and the latter may be reached by splitting the *columna* mesially.

The **anterior nasal orifice** is the heart-shaped anterior or facial aperture of the bony nasal fossæ *measuring*  $1\frac{1}{4}$  inches vertically and a little less transversely, in its widest part. It can be palpated by the finger introduced through the nostril. The portion of each nasal fossa between the anterior nasal orifice and the nostrils is called the **vestibule** and differs from the rest of the fossa in being covered by the cartilaginous part of the nose and in being lined by a squamous epithelium. This is beset near the nostrils with stiff *hairs* which serve to *filter* the air and arrest particles of dust. It is also provided with sebaceous glands and is liable to eczema and to painful furuncles originating in the glands, etc.

The **posterior nares** are symmetrically placed on either side of the posterior border of the nasal septum, which forms their mesial boundary. They *measure* 1 to  $1\frac{1}{4}$  inch vertically and one half inch transversely in the skeleton, but these measurements are reduced somewhat by the covering of mucosa and, in the upper and outer aspects, by the projection of the Eustachian tube. They may be seen with difficulty by *posterior rhinoscopy*, in which a small mirror is introduced behind the soft palate. Through this can be seen, under favorable circumstances, the posterior part of the septum, the turbinate bones and meatuses, also the Eustachian tubes and the upper part of the pharynx. The same parts may be felt by the finger introduced through the mouth and above the soft palate. The *posterior nares* are sometimes **plugged** to arrest bleeding from the nose. For this purpose a pyramidal plug of several folds of gauze is made whose base measures a little more than the posterior nares. This is threaded with two ligatures from the apex and one from the base and pulled up into place from behind by means of a cord which has been passed through the inferior meatus into the pharynx and out through the mouth by a Bellocq's sound or a soft catheter. The two cords pass out through the nostril and are there tied tightly over a plug in the nostril, thereby plugging the latter and holding the posterior plug snugly in place. The single cord from the base of the plug is passed out through the mouth to be used in withdrawing the plug. The same object may usually be accomplished by inserting a strip of gauze through the nostril and packing it well into the nasal fossæ.

The **nasal fossæ** (Fig. 19) *lie* beneath the cranium, above the mouth and between the orbits and maxillary sinuses. They are very *narrow* above but widen out somewhat below, so that while there intervenes a space of 4 to 5 mm. between the inferior turbinate bone and the septum, only 2 mm. intervenes between the latter and the superior turbinate

bone. In fact, the latter space is so narrow that surgically the superior turbinate bone practically forms the roof of the nasal fossæ. Owing to the narrowness of the fossæ polypus or other *forceps* are best introduced so as to be opened vertically.

The **floor** is the widest part of the nasal fossæ and measures at its center, or widest part, 12 to 15 mm. in width. It is smooth, concave from side and slanted slightly downward behind, so that in the erect position secretions drain backward to the pharynx.

The **roof** is extremely *narrow*, 2 to 3 mm., so that surgical exploration or operation here is nearly out of the question and there is little danger of its penetration by anything as large as a polypus forceps. Yet it has been *perforated* by slender bodies, by accident or design, and the cranial cavity thereby opened through the cribriform plate. In such cases, or in fracture of this plate involving the mucosa beneath it, there is bleeding from the nose, the discharge of cerebrospinal fluid, if the subarachnoid space is opened, and the danger of meningitis, as it is impossible to make and keep the nose aseptic. In fact meningitis has resulted from the extension of inflammation through an intact nasal roof in case of inflammation of the nose. *In front* of the cribriform plate the roof slants downward. It is here formed by the nasal bones and the nasal spine of the frontal, and above the latter lie the frontal sinuses. *Behind* the cribriform plate the roof slants more abruptly downward and is formed by the anterior surface of the sphenoid containing the openings of the sphenoidal sinuses. It follows that the *height* of the fossæ is greatest about their center.

The **median wall or septum** is straight in children up to the seventh year but in adults it *deviates* to one side, in over 75 per cent. to the left. A deviation may follow an injury but this is not the common cause. The nose as a whole is seldom absolutely straight and this has been attributed to blowing the nose with the same hand, usually the right, sleeping largely on the right side, etc. The septal deviation involves the bony and the cartilaginous portions and if it is marked it may more or less block one nasal fossa by contact with the turbinate bodies. This *contact* is a source of constant irritation and may result in fusion of the parts (*synechia*). Until we examine the opposite fossa and note the concavity of the septum we may mistake the deviation of the septum for a septal tumor, abscess or haematocele or even a nasal polyp. There are many *operations* for the restoration of the blocked fossa or the straightening of the septum. Exostoses or "*spurs*" are liable to grow on the septum, especially at the junction of the bony and cartilaginous portions. As the septal cartilage is the principal support of the cartilaginous part of the nose its destruction by syphilis causes a great flattening of this part of the nose. Syphilitic destruction of the bony and cartilaginous septum and of the adjacent bones may result in the flattening of the bony vault also.

The **mucosa** covering the *septum* is blended with its periosteal and perichondral covering into a single dense layer, and the layer thus formed is loosely attached to and easily separated from the septum.

Hence collections of blood or pus may readily form beneath the mucoperiosteal covering; also by stripping up the latter the septum may be exposed and operated upon without entering the nasal cavity.

The outer wall (Fig. 20) has a general slant from above downward and outward. The anterior end of the inferior turbinate bone reaches to the junction of the bony and cartilaginous part of this wall and within about 2 cm. of the nostril. The posterior end of this bone is at the posterior nares, on a level with the opening of the Eustachian tube. The free border of the inferior turbinate bone may extend so far toward the floor of the nasal fossa as to interfere with the introduction of instru-

FIG. 20.

ments along the **inferior meatus**. The latter is the *widest* part of the nasal fossae, measuring about one half inch. Its greatest *height* (three fourths inch) corresponds to the opening of the *nasal duct*, which is about 1 to  $1\frac{1}{2}$  inches behind the nostril. This opening lies just beneath the attached border of the inferior turbinate bone at the meeting of its anterior fourth, which is slanted sharply downward and forward, and its posterior three fourths, which are slanted more gradually downward and backward (see also p. 65). The sharp downward slant of the anterior fourth of the inferior turbinate bone renders the *height* of the inferior meatus but little in front and less here than it is behind. Hence *inspired air* is not so apt to enter this meatus, *expired air* more apt to. This tendency is increased by the downward direction of the

nostrils, the consequent upward current of inspired air, the wide funnel-shaped anterior end of the middle meatus (*the atrium*) and the narrowed posterior end of this meatus. This explains the fact that we *smell inspired air*, for it passes through a meatus (middle) part of whose walls is supplied by the olfactory nerves, as well as the fact that we do not smell expired air, for it passes largely through the inferior meatus which the olfactory nerves do not reach. Also if we wish to *smell* an object we dilate the nostrils and sniff up the air which thereby is carried into the upper olfactory part of the fossæ.

The anterior end of the **middle turbinate bone** inclines upward so that it reaches the *level* of the inner canthus of the eye. This upward inclination makes the **middle meatus** open up widely in front into the **atrium**, into which an instrument, introduced through the nostril, passes more readily than into the inferior meatus, unless care is taken. About the center of the middle meatus is the slit-like *opening of the antrum*, about one inch above the floor of the nasal fossa and nearer the roof than the floor of the antrum. This opening is at the lower end of a deep groove, the *infundibulum*, which curves downward and backward, beneath the attached margin of the superior turbinate bone, from the opening of the canal leading from the *frontal sinus*. Into this groove open also the anterior *ethmoid cells*.

The **mucous membrane** varies in different parts of the nasal fossæ. Behind the vestibule the nasal fossa is divided into an upper *olfactory region* including the middle and upper turbinate bones and the upper third of the septum, which is covered by columnar epithelium, and a lower *respiratory region* including the rest of the fossa, which is covered by columnar, ciliated epithelium. On the outer wall between the turbinate bones and on the floor the mucosa is thin, elsewhere it is thick and vascular, especially over the turbinate bones. This *thickness* over the turbinates is largely due to the abundant submucous *venous plexus*, the meshes of which run mostly antero-posteriorly. The mucous membrane extends in a fold beyond the inferior turbinate bone in front, behind and below. Over this bone the veins of the thick mucosa form a kind of cavernous or *erectile tissue*. This may swell up rapidly from engorgement of the veins so as to come in contact with the septum and this contact is in itself a source of irritation. The rapid shrinkage of this "erectile body" when a caustic like chromic acid is applied to it is very striking.

The *acinous glands* of the mucosa, secreting for the most part a thin watery fluid, are most numerous over the inferior turbinate bone and the middle and posterior parts of the fossæ. They account for the profuse secretion in *coryza*. The normal *function* of this *secretion* appears to be to moisten the inspired air, that of the great *vascularity* of the mucosa to warm the inspired air. *Adenoid tissue* is abundant in the mucosa of the posterior part and is continuous with that of the nasopharynx. Several of the *openings* found in the bony fossæ are closed by the mucosa. From the relations of the nasal fossæ and the continuity of its mucosa with that of other parts it follows that *inflamm-*

mation of this mucosa (*coryza*) may spread through the posterior nares to the pharynx and to the Eustachian tubes, through the nasal duct to the lachrymal sac and conjunctiva and through the infundibulum to the frontal and maxillary sinuses and the ethmoid cells. One or more of these extensions is often exemplified in a *coryza*.

Swollen turbinate bones may be mistaken for **mucous polypi** which are common in the nose and usually arise from the inferior or middle turbinate bones. They often grow in crops, block the fossæ and may press upon and widen the nose or obstruct the opening on its outer wall. They may be *removed* with the snare or polypus forceps, care being taken not to damage the cribriform plate in case of high attachment. The fibrous and sarcomatous polypi take origin as a rule from the periosteum of the roof of the nose or pharynx and spread in all directions.

The **blood supply** of the nose is derived from three sources, the ophthalmic, facial and internal maxillary. The *veins*, in addition to accompanying the arteries, communicate with the superior longitudinal sinus through the foramen cecum in children and sometimes in adults. This communication and that with the cavernous sinus through the ophthalmic veins help to explain intracranial complications in some cases of inflammation of the nasal cavities.

**Bleeding** from the nose, or *epistaxis*, may be due to fracture or other injury, general oozing of the vascular mucosa, ulceration or venous congestion, as in cardiac or pulmonary disease. In the latter case the patient should be kept erect to aid venous return and the raising of the arms is recommended on account of the resulting expansion of the thorax and its aspiration upon the cervical veins. In some cases the bleeding is vicarious. The *ulcerations* are apt to be on the *septum*, where they should be sought for. Nose bleed may be *profuse* and *long continued*; as much as 75 lbs. of blood has been lost altogether (Fränkel), and it has continued for twenty months on and off (Spencer Watson). If it resists local applications *plugging* of the nares or nasal fossæ (p. 75) may have to be employed to arrest a fatal result, which has occasionally occurred. The great vascularity of the nasal mucosa accounts for the frequent occurrence of epistaxis.

The **lymphatics** communicate through the cribriform plate with the subdural space and also enter the submaxillary, parotid and retropharyngeal nodes. Abscess of the last-named nodes may therefore be due to disease of the nose, and in lymphadenitis of the cervical nodes we are forced by exclusion in many cases to assume, if not to prove, that the source of infection was in the nose or nasopharynx.

The **nerve supply**, apart from the olfactory nerve whose distribution has been given above, is from the first and second divisions of the *fifth nerve*. The *nasal branch* of the *ophthalmic division* of the fifth nerve supplies the antero-superior part of the nasal fossæ and explains the following *reflexes* in connection with other branches of this division of the nerve; *i. e.*, the *lachrymation* that may follow a pungent odor and the *sneezing* from looking at bright sunlight. In the

former case the irritation is referred to the lachrymal branch of the same division and in the latter case it is referred from the nerves of the orbit to the nasal branch. *Sneezing* also follows the direct irritation of the nerves of the nose by chemical or mechanical irritants like snuff or dust or the abnormal contact of the septum and outer wall of the nose. Curious accidents have occurred during violent acts of sneezing. Thus Treves mentions fracture of the ninth rib, dislocation of the shoulder, and rupture of all the coverings of a large femoral hernia.

The lodgment of **foreign bodies** in the nose is quite common. That they may remain in some cases for long periods of time without causing much trouble is illustrated by a case reported by Tillaux of an old woman from whose nose he removed a cherry stone that had lodged there for twenty years. When they remain long they may become encrusted by calcareous matter and thus form rhinoliths which are most common in the lower meatus. In some cases of chronic purulent discharge from one nostril the cause may be the presence of a bean, bead, button or other foreign body in the nose.

The **nasal douche** may be used in more than one way. Thus with the head lowered a little and the mouth open the nozzle of the irrigator is introduced into one nostril and the fluid flows out of the other after passing from one fossa to the other behind the posterior nares. This is possible from the fact that in breathing through the mouth the palate is elevated so as to continue in line with the nasal floor behind the posterior nares and shut off the nasal fossa from the pharynx. But at the same time the Eustachian tube is opened by the same mechanism that raises the palate and there is some danger of infection being carried into it. Again, with the head tilted slightly backward, the douche may be allowed to flow back until it reaches the pharynx, the mouth being kept closed.

### The Accessory Sinuses of the Nose.

The **frontal sinuses** do not exist at birth but their evolution occurs between the seventh and twenty-first year. They may be considered as *developed* from the diploë and hence lie between the inner and outer tables of the skull, or they may be considered as prolongations of the ethmoid cells. They are *situated* above and external to the nose, above and internal to the orbits, and beneath and in front of the cranial cavity. They lie on either side of the glabella and behind the *superciliary ridges* whose prominence they form. But the absence of these prominences does not necessarily imply absence of the sinuses as they may extend backward only. The orbital and cranial walls of the sinuses are formed by thin bony lamellæ. The sinuses are divided into two lateral halves by a *septum*, often incomplete and sometimes wanting, which is median inferiorly but deviates to one side above. Sometimes they are so small as to be scarcely noticeable, at other times they may be large enough to contain two or more ounces, or to contain a foreign body of some size. In *old people* these sinuses may

enlarge as the brain shrinks. Well-developed sinuses may extend 2 inches upward,  $1\frac{1}{2}$  inches outward and nearly as far backward. In *injury* to this region there may be a *depressed fracture* without damage to the cranial cavity, in which case *air* may be forced through the opening on blowing the nose and cause frothing of the blood if the fracture be compound, or subcutaneous emphysema in a simple fracture. In the adult therefore fracture here is less serious than elsewhere on the skull, as the brain case may be spared.

The frontal sinuses are lined by a pale, thin, loosely adherent *mucosa* continuous with that of the nose, through the infundibula, and liable to extension of *inflammation* from the nose. Hence the frontal *headache* in some cases of coryza, ozoëna, etc. The *infundibular passage* is deeply placed near the inner wall of the orbit and opens into the infundibular groove about on a line with the *tendo oculi*. By the swelling of the mucosa of the infundibulum its lumen is temporarily occluded. When pus forms we have *empyema* of the frontal sinus or sinuses. Eventually in such cases the walls give way at their weakest point, which in 90 per cent. of cases is the orbital roof, and the abscess discharges through the inner half of the upper lid. Occasionally the posterior wall of the sinus is eroded and perforated, giving rise to a subdural abscess or pachymeningitis, or in some cases meningitis or brain abscess.

The frontal sinuses require *opening* by the chisel, burr or trephine in cases of *empyema* and may be reached by a vertical *incision* which avoids the vessels and nerves of this region. This incision is made in the median line to open both sinuses or laterally, either internal or external to the supraorbital notch, to open a single sinus. The reëstablishment of drainage into the nose is most desirable.

In some curious cases insects like centipedes, larvae and even maggots have found their way into the frontal sinuses; in the latter case setting up a violent septic inflammation. Bony tumors may grow from the fibrous layer lining the deep surface of the mucosa.

**The antrum of Highmore** or *maxillary sinus* (Figs. 16 and 19) is present at birth, but continues to grow until old age when its walls become very thin. It occupies the body of the maxilla and is pyramidal in *shape* with its base internally toward the nasal fossa. Its anterior or *facial wall* is the thickest but the most accessible so that the *opening* of an *empyema* of the antrum is usually made on this surface above the first or second molars, after incision of the mucous membrane where it is reflected from the gums to the cheek. Inflammation and *empyema* of the antrum may be due to the diseased root of a tooth, especially that of the first and second molars. The *roots* of the latter *teeth* often cause a *prominence* in the lower part of the antrum and may even project uncovered into it. In diseased conditions the sockets of almost any of the teeth may communicate with it. When the diseased root of a first or second molar is drawn it may open and drain the antrum from its lowest point but this method of drainage as an operation of choice has the disadvantage that it allows food particles to enter the

antrum. Behind the antrum is the **sphenomaxillary fossa** (Fig. 19) containing **Meckel's ganglion**, to remove which the route through the antrum, after resecting its facial and zygomatic walls, has been tried. The upper wall separating it from the orbit is very thin so that tumors of either of these cavities readily extend into the other. As this wall contains the *infraorbital nerve*, in a groove and canal, and the anterior and posterior walls contain the nerves of the upper teeth, tumors, etc., which press upon these walls are likely to cause neuralgia of the face and teeth. The inner wall or base corresponds to the outer wall of the nose in the inferior and middle meatuses, in the latter of which at the lower end of the infundibular groove is the *orifice* of the antrum. As this is above the middle of the cavity it is not arranged for drainage. Sometimes, in perhaps 10 per cent. of cases, there is another opening a little further back which is pathological in many cases. This wall is so thin as to be readily perforated. The mucosa of the nasal fossa is continuous with that of the antrum and in this way inflammation may extend from the nose to the antrum. The mucosa of the antrum resembles that of the frontal sinus but is somewhat more vascular and more richly supplied with mucous glands. The latter are quite prone to cystic formation whereby the antrum may be partly or wholly filled, a condition sometimes erroneously called dropsy of the antrum.

Tumors of the upper jaw may originate in the antrum or grow with great rapidity on entering it, and in either case they *distend its walls*. Thus, pushing up the roof, they invade the orbit, and breaking through the thin inner wall, they obstruct the nasal fossa. They also protrude through the bottom of the antrum onto the roof of the mouth and form a projection on the cheek. The only treatment for such conditions is the excision of the upper jaw. In one case of *fracture* of the anterior wall of the antrum under my care *emphysema* of the cheek was present and was increased on blowing the nose. Occasionally the antrum is subdivided by bony septa into recesses or separate chambers.

As to the **sphenoidal sinuses** little need be said except that like the other sinuses of the face they serve the purpose of lightening the face so that in spite of its growth the equilibrium between the anterior and posterior parts of the head at its articulation with the spine is not disturbed. Also, like the maxillary sinus, it may have some effect on the quality of the voice, acting like a sounding box. *Fracture* through them leads to bleeding from the nose and may establish a communication between the latter and the cranial cavity. Dense *exostoses* occur within them as within the frontal sinuses.

### THE FACE.

This region, apart from the eyebrows, eyelids and nose, already studied, and the parotid region and lips, to be considered later, we will study layer by layer. The *lower limit* of this region and the boundary between it and the neck is the lower border of the lower jaw.

The skin of the face is for the most part thin, fine and very vascular. Its *vascularity* is seen in the ready flushing of the cheeks, in blushing and fever; in the free bleeding and rapid healing of wounds or incisions; in the varicose or injected condition of its fine vessels in those exposed to cold and in the subjects of alcoholism and acne; and in the common occurrence of nævi and various forms of vascular tumors. As the skin is richly supplied with sebaceous and sweat glands it is a favorite site for acne and *sebaceous cysts*. The latter sometimes require the use of the knife to avoid a more disfiguring scar. The skin of the face is also a favorite situation for the development of *epithelioma* and *lupus*. Over the *chin*, from the median line to the posterior border of the depressor angularis muscle, the skin partakes of the character of that of the scalp, or more nearly that of the eyebrows, for instead of a fibroadipose subcutaneous layer, as in the scalp, we have muscle fibers of several intersecting muscles attached to the skin interspersed with small pellets of fat. Here too as in the scalp the skin is thick and dense and contains numerous hairs and sebaceous glands, and the arterioles, adherent to the parts through which they pass, are difficult to seize with the artery clamp. When the skin of this part or that covering the malar bone is struck by a blunt instrument or in a fall a wound may be produced simulating an incised wound, as is also the case with the scalp.

The **subcutaneous layer** is in general *lax* so that on the one hand it favors the spread of inflammations, *œdema*, etc., and on the other hand it increases the mobility of the skin and renders it suitable for the various plastic operations done here. In *inflammation* or *œdema* the face may be greatly swollen and in the latter condition the swelling first appears, as a rule, in the loose subcutaneous tissue of the lower lid. The quantity of fat in the subcutaneous tissue varies in different parts and under varying circumstances. Thus it is especially abundant in the *cheeks*, or those lateral regions corresponding to the area lined by the mucous membrane on the inner surface. It is firmer and more abundant in children and well nourished persons, more scanty in old age and after wasting diseases, as indicated by hollow cheeks and prominent cheek bones. Fatty tumors are exceedingly rare here.

In this layer lie the main **blood vessels** of the face, the principal branches of the *facial nerve*, (in front of the anterior border of the masseter), a *lymph node* near the lower border of the mandible and the facial muscles of expression. The **facial artery**, where it crosses the lower border of the mandible at the antero-inferior angle of the masseter, lies just anterior to its *vein* and is covered by the skin and platysma only. Here its pulsations can be easily felt and it can be readily compressed against the bone or ligated. In passing towards the angle of the mouth and the ala of the nose and thence up beneath the nasofacial groove it describes the arc of a curve whose cord is formed by the straighter and more superficial **facial vein**. The free communication of the latter with the cavernous sinus through the

ophthalmic vein explains the danger of intracranial complications like sinus-thrombosis, in case of septic processes of the face, such as carbuncle, erysipelas, malignant pustule, etc., especially when they occur near the course of the facial vein, along which they may spread as a phlebitis or periphlebitis.

*Malignant pustule*, a disease transmitted from cattle, attacks the face, on account of its free exposure, more often than any other part (even the hands). Also in the young a form of gangrene, *cancrum oris*, sometimes attacks and extensively destroys the soft parts of the cheek to such an extent that in some cases the jaws may be firmly closed by the contraction of the resulting scar. Owing to the free blood supply *extensive flaps* in plastic operations, or even those torn up in lacerated wounds, keep their vitality in a very remarkable manner. As the *anastomosis* is very free between the two sides of the face or two adjoining branches of the artery both ends of a divided facial artery must be sought and tied to check bleeding. The *lymph node* near the vessels as they cross the border of the mandible, is often enlarged in cases of alveolar periostitis, etc., from dental caries. Abscess in this region not infrequently originates in this way.

**The Nerves.**—The branches of the **facial nerve** are nearly horizontal in direction. They *anastomose* and form plexuses with the infraorbital, mental and buccal branches of the fifth nerve. The facial nerve *supplies* the muscles of expression, hence in **facial paralysis** there is a lack of expression on the side paralyzed, the lines of the face are flattened out and the surface is smoother than normal. The *cause* of the paralysis may be within the brain, in the passage of the nerve through the skull, in the aqueduct of Fallopian, or external to the skull. The *symptoms* help us to determine the *position of the lesion* according as one or another branch, given off along its course, is affected or not. Thus, if the *palate* can not be elevated or shortened on the side paralyzed, the lesion is thought to be internal to the geniculate ganglion from which the *great superficial petrosal* nerve passes to Meckel's ganglion and, according to many, from thence by palatine branches to the levator palati and azygos uvulae muscles. On the contrary, if these muscles act the lesion is thought to be distal to the geniculate ganglion. Again, if the *taste* is lost on one side of the front of the tongue the lesion is proximal to, if it is not lost it is distal to, the origin and giving off of the *chorda tympani* branch in the lower part of the Fallopian aqueduct, for this branch conveys taste fibers from the glossopharyngeal nucleus to the tongue. Just below the aqueduct there is given off the *posterior auricular branch* which supplies the posterior belly of the occipitofrontalis and the retrahens and attollens aurem so that these muscles are paralyzed if the lesion is proximal to this branch but not if it is distal to it, and so on.

As the *orbicularis palpebrarum*, *frontalis* and *corrugator supercili* muscles are not involved in facial paralysis due to a lesion of the cortical facial center, it is probable that the fibers which supply them reach the facial nerve from the *oculomotor nucleus*. Also the involve-

ment of the *orbicularis oris* in bulbar paralysis and the close association of the movements of the lips and tongue suggest that this muscle is supplied from the *hypoglossal nucleus* through the facial.

The chief features of *facial paralysis* are the inability to wink or close the eye, so that the cornea is always exposed, the dripping of tears over the cheek (see p. 63), a flabby cheek between which and the gums food lodges, the inability to whistle or pucker the mouth and an expressionless corner of the mouth, with or without partial loss of taste and paralysis of the palate muscles. *Electricity* can be applied to the nerve or its branches; to the undivided trunk by an electrode pressed as deeply as possible between the mastoid process and the cartilaginous auditory meatus.

Below its exit from the stylomastoid foramen the facial nerve is accessible to surgical procedure through a curved incision in front of the mastoid process and the sternomastoid muscle. The latter is retracted backward and the parotid gland forward, and by blunt dissection the styloid process is reached, behind which the nerve emerges.

Though the main trunks of the sensory nerves belong to the deepest layer of the face their filaments pass through the subcutaneous layer to reach the skin. To complete the study of the nerves of the face they are best considered here. They are branches of the *fifth nerve* and three such branches concern the region under consideration. The *infraorbital branch* of the maxillary (second) division of the fifth nerve, after passing along a groove and then a canal in the floor of the orbit (and the roof of the antrum), emerges on the face at the *infraorbital foramen*. This is situated at the upper end of the canine fossa, one third of an inch below the inferior margin of the orbit, near the junction of its middle and inner thirds and in a vertical line from the interval between the two upper bicuspids or from the second bicuspid. When, as sometimes occurs, it is the seat of an obstinate neuralgia it may be reached and resected either by *incising the mucous membrane* above the bicuspids and separating the soft parts from the bone, or by a curved or angular *cutaneous incision* below the orbit. By lifting up the contents of the orbit from its floor the nerve is exposed in the bony groove in which it lies and that part of it may be resected which lies between the groove and the foramen. The small arterial branch accompanying the infraorbital nerve may usually be disregarded.

**Meckel's ganglion** has often been *resected* for certain neuralgias of the second division of the fifth nerve by following the infraorbital nerve backward. Thus, after *incising* through the lip and along the nasolabial and nasofacial grooves, a flap of skin is turned up and the anterior wall of the antrum opened, up to the *infraorbital foramen*. The bony canal and groove of the nerve is then laid open from beneath and, following the nerve, the posterior wall of the antrum is trephined, opening into the *sphenomaxillary fossa*. (Fig. 17.) This exposes the triangular reddish ganglion one fifth of an inch in diameter, lying below the main nerve. The terminal branches of the internal maxillary artery are in close relation to the ganglion. External to it is the

external pterygoid muscle, internal to it the vertical plate of the palate bone and the sphenopalatine foramen. Behind the ganglion the nerve trunk can be followed back to the foramen rotundum.

The mental branch of the *inferior dental trunk* of the mandibular division of the fifth nerve emerges at the *mental foramen*, below the interval between the two lower bicuspids or below the second bicuspid. It is thus seen to lie in the same vertical line with the infraorbital foramen and if this line is continued upward it strikes the supraorbital notch or foramen. Hence these three branches of the three divisions of the fifth nerve emerge through bony openings in the same vertical line. The mental foramen in the adult is midway between the lower and the alveolar borders of the jaw, in the aged near the latter, in the infant near the former. It may be *exposed* by a cutaneous *incision* or by one through the gingivolabial fold of mucous membrane, remembering that the foramen lies one third of an inch below this fold.

The main trunk of this nerve, the *inferior dental*, may be *exposed* for exsection at its entry into the *inferior dental foramen* in one of several ways. The foramen, it should be remembered, is about *equidistant* from all four borders of the ramus, that is about the center of the inner surface. Surmounting the foramen in front is the *mandibular spine* to be used as a landmark when we expose the nerve at its entrance into the foramen. This is done from *within the mouth* by *incising* the *mucous membrane* from the last upper molar to the inner side of the coronoid process, thus exposing the tendon of the temporal muscle. The finger is then introduced backwards between the ramus of the jaw and the internal pterygoid muscle till the mandibular spine is felt. Thereupon the nerve is hooked forward by a blunt hook, isolated from its accompanying vessels and divided, or a piece cut out of it.

From the *outside* we may expose the nerve by an angular *incision* of 3 cm. upward and 5 cm. forward from the angle of the jaw. The periosteum of the borders of the ramus is divided to the same extent and then stripped up from the inner surface until the mandibular spine is reached. Again it may be exposed by *resection of the angle* or posterior border of the ramus of the jaw, or by a vertical incision over the middle of the ramus, retracting Stenson's duct upward, separating the fibers of the masseter, dividing the periosteum in the same line and *trepining* or chiselling through the *center of the ramus*. In all external vertical incisions great care must be taken to avoid Stenson's duct and the facial nerve.

The *buccal nerve* (Fig. 21) is another sensory branch of the fifth nerve, sometimes affected by neuralgia which is felt in the skin and mucosa of the cheek and lips. It may be *exposed* from *within* or without the mouth. As the nerve courses forwards on the inner surface of the temporal muscle, near its insertion on the coronoid process, it is only *covered* by the mucous membrane, buccinator muscle and fatty tissue, so that it may be exposed by dividing the latter layers vertically behind the last molar. From the *outside* it may be exposed by a transverse *incision* of 5 cm. over the course of Stenson's duct (see p. 87).

PLATE V.

FIG. 21.

Zygomatic fossa and adjacent parts as seen  
when exposed from the vestibule of the mouth.  
(Zuckerkandl.)

Stenson's duct and accompanying nerves are retracted upward or downward, the fatty tissue (Bichat's lobule) between the buccinator and masseter is removed or retracted and the nerve is seized opposite the insertion of the temporal muscle, about  $2\frac{1}{2}$  cm. behind the anterior border of the masseter.

In this or any *operation on the face transverse incisions* are preferable and vertical incisions objectionable because of the danger of wounding important structures having a transverse course. These are the branches of the facial nerve, already mentioned, and the duct of Stenson whose course is given below. This, the excretory duct of the parotid gland is beneath the **deep fascia**, which forms the next of the several layers of this region. This fascia is continued forward from the parotid gland, of which it forms the sheath. The two layers of the parotid sheath unite and form the fascial covering of the masseter and, in front of this, of the buccinator. Beneath the masseteric fascia lie the branches of the facial nerve which (except the buccal branches) pierce it at the anterior border of the muscle.

**Stenson's duct**, one eighth of an inch in *diameter*, extends forward for 2 to  $2\frac{1}{2}$  inches from the anterior border of the parotid gland to the *opening* of the duct on the buccal mucosa, *opposite* the crown of the second molar, 4 mm. below the reflection of the mucosa from the gums to the cheek and about 33 mm. behind the angle of the mouth. The course of the duct is a finger's breadth or three quarters of an inch below the zygoma or in a line from the tragus of the ear to the midpoint of the upper lip. The posterior or *masseteric portion* crosses the middle of the masseter, having the *socia parotidis* above or superficial to it, the *transverse facial artery* above it, and the *buccal branch* of the facial nerve below it. It then bends sharply inward through the fat of the cheek to the buccinator muscle through which the anterior or *buccal portion* runs obliquely forward and then for a short distance between the muscle and the lining mucosa to its termination.

The *bends* in its course should be remembered, for in passing a probe through it they should be straightened out by pulling forward the angle of the mouth. The course of the duct should be particularly remembered so as to avoid it in any incision in the cheek, for its *division* may be followed by an obstinate **salivary fistula**. This is particularly troublesome in the posterior or masseteric portion where the only successful conservative treatment is an anastomosis between the divided ends, a difficult matter on account of its small size. In the anterior or buccal portion of the duct a salivary fistula may be successfully treated by stitching the proximal end of the duct into an opening in the buccal mucosa, made by incising through the buccinator, behind its normal opening.

The duct is surrounded by a **fibrous sheath** continued forward from the parotid sheath and by a fibrous sheath of its own. Both of these sheaths leave it where it penetrates the buccinator and there become continuous with the fascial covering of this muscle. *Inflammation* may travel back along the duct from the buccal cavity to the gland,

in case of stomatitis in the former. It is not unlikely that this is the route of infection in some cases of acute parotitis complicating acute infectious diseases. Hence the importance of antiseptic mouth washes in these conditions.

Between the buccinator and its fascia and behind Stenson's duct is a group of deep buccal or *molar glands* which may be the origin of cysts or adenoma. They are opposite the last two molars. Behind these and filling the space between the buccinator and the masseter is a *pad of fat*, the buccal fat pad or "*Bichat's lobule*." This is quite constant, even in emaciated conditions, but if it be absorbed in wasting diseases a marked hollow of the cheek is produced in front of the masseter. A swelling, from *lipoma* or *abscess* in this situation, *points* in the mouth, as it is beneath the buccal fascia. In case of abscess it is to be noticed that this *fat* is *continuous* with the fat and loose areolar tissue in the temporal and zygomatic fossæ and that which covers the upper part of the pharynx. The *mucous membrane* lining the buccinator is thin and directly adherent to the muscle without submucous tissue between.

### The Parotid Region.

This is *bounded superficially in front* by the posterior border of the mandible; *behind* by the mastoid process and sternomastoid muscle; *above* by the auditory meatus, the condyle of the jaw and the posterior part of the zygoma; *below* by a line from the angle of the jaw to the sternomastoid muscle, outlined by a thickened band of the cervical fascia. The surgical anatomy of this region is most important on account of the important parts in relation or contiguity with the parotid gland which occupies it.

This gland is *lodged* in a narrow and deep but well-defined space, the **parotid compartment**, which is *bounded* as follows: *behind* by the sternomastoid, the posterior belly of the digastric and the mastoid process; *in front* by the posterior border of the ramus of the jaw, covered by the masseter and internal pterygoid muscles; *above* by the external auditory meatus and the posterior part of the glenoid fossa; *below* by the stylomaxillary ligament which separates the parotid from the posterior end of the submaxillary gland; *internally* by the styloid process and its muscles, which separate it from the internal carotid and internal jugular, with their accompanying nerves, and, in front of these, from the loose tissue around the pharynx. Internal to the parotid space and in front of and below the tip of the mastoid may be felt the *transverse process of the atlas*, covered in part perhaps by the posterior belly of the digastric.

Within these limits the parotid is enclosed within a distinct **sheath** which is derived from the deep cervical fascia. At the anterior border of the sternomastoid the fascia which has formed the sheath of the muscle, divides into two layers, one of which passes internal and the other external to the gland. These layers unite in front of the gland to become continuous with the fascia covering the masseter; and below the gland they unite along the thickened band between the angle of

## PLATE VI.

FIG. 22.

Horizontal section through the left parotid compartment. Diagrammatic. Arrow indicates the pharyngeal opening of the compartment. (Testut.)

FIG. 23.

Frontal section through the right parotid compartment to show its relations. Diagrammatic. Arrow indicates the pharyngeal opening of the compartment. (Testut.)

the jaw and the sternomastoid muscle. From this band the inner layer passes inward and upward on the outer aspect of the styloid process and its muscles, forming the sheath of these muscles and becoming attached to the styloid process.

*Internally the parotid sheath is deficient* in front of the styloid process, between it and the internal pterygoid muscle, where an uncovered prolongation of the gland projects inward into relationship with the pharyngeal wall in front of the great vessels, etc. Hence *abscess or tumors* of the parotid are unopposed by the sheath in spreading inward toward the pharynx. Conversely in postpharyngeal abscesses there is often a parotid swelling and sometimes the abscess evacuates through the parotid. *Anteriorly* there is a process of the gland, *socia parotidis*, prolonged forward a variable distance on the surface of the masseter, above or overlying Stenson's duct, and, like the latter, covered by a prolongation of the parotid sheath. In inflammation or tumor of the parotid therefore the swelling may extend forward onto the surface of the masseter. *Superiorly* the sheath is *incomplete*, being attached externally to the inferior border of the zygomatic arch and the outer part of the cartilaginous auditory meatus, internally to the base of the styloid process, the free border of the vaginal process and the Glaserian fissure. Hence between the outer and inner layers of the sheath superiorly the gland is in *direct contact*, without intervening fascia, with the *external auditory meatus* and the posterior part of the glenoid fossa. This accounts for the ease with which *inflammations* of the parotid extend to the *external auditory meatus* or the periosteum of the adjacent bones (see also pp. 49 and 50).

As a portion of the gland occupies the posterior part of the glenoid fossa it comes in direct *relation* with the capsule of the *temporomandibular joint* and explains in part the *pain* of moving the jaw in cases of parotid inflammation, like mumps, abscess, etc., and the occasional extension of inflammation of the gland to the joint. The pain is also accounted for by the fact that the anterior limit of the parotid compartment is formed by the movable ramus of the jaw and the masseter and internal pterygoid muscles covering it, so that in movements of the jaw, like retraction or opening, the space is encroached upon and the gland pressed upon by the ramus or its angle and the pain of an inflamed parotid is aggravated.

The fact that the *size* of the *parotid compartment*, and especially that of its superficial boundaries, is *altered* by the position of the jaw, which occupies a groove on its anterior surface, should also be remembered in *operations* on this narrow region in which we need all the space available. Thus it may be *increased* antero-posteriorly by about three eighths of an inch by a simple protrusion of the jaw and to a certain extent by extension of the head whereby the sternomastoid is separated from the ramus. It is *narrowed* in the opposite movements. In opening the mouth it is narrowed inferiorly but widened superiorly by the gliding forward of the condyle. The obliquity of the ramus in infancy and old age widens the lower part of the space.

The strength of the fascia superficial to the parotid offers much resistance to the spontaneous opening of a parotid abscess in this direction. In addition to the directions indicated above an *abscess* may also *extend* downward to the neck, upward into the temporal fossa, or forward toward the buccal cavity, internal to the ramus where the sheath is weaker and is penetrated by the carotid. Pus within the gland may also occasionally escape along a vessel or nerve where it perforates the investing fascia.

From the inner surface of the enveloping fascial sheath fibrous processes extending inward divide the gland into *lobules* and support the vessels and nerves which pass through it or supply it. To these *trabeculae* the *vessels adhere* so intimately that it is practically impossible to remove the gland and spare the vessels. Although the *nerve trunks* are less intimately adherent, yet in the living subject, especially where the entire gland is occupied by a tumor, it is impracticable if not impossible to remove the gland and spare the nerves also. This fibrous framework is the seat of the inflammation in the *specific parotitis* known as *mumps*. Acute parotitis also occurs as a *complication* in septic or pyæmic conditions ; during acute infectious diseases, such as typhoid fever and more rarely pneumonia, and after injuries and diseases of the abdomen and pelvis. Abscess formation is to be expected in such conditions and the pressure on the small vessels may occlude them and cause a necrosis of the lobules of the gland supplied by them.

Contained within and passing through the gland are many important structures. The **facial nerve** passes forward through the gland from the postero-internal aspect with an inclination outward and slightly downward. Its *entry* into the parotid corresponds to the point where the anterior border of the mastoid meets the external auditory meatus. It *lies* superficial to the main arterial and venous trunks and breaks up, after an undivided course of about 2 cm. into a *plexus* which emerges at the anterior border of the gland, after being joined by branches of the **auriculotemporal nerve**. The latter sensory branch of the inferior maxillary division of the fifth nerve *passes* from within upward and outward through the upper part of the gland to *emerge* at its upper border. Thence it *crosses* the root of the *zygoma* between the ear and the temporal artery where it may be exposed and resected. The *pain* of a parotitis and of some parotid tumors may be referred along the course of the auriculotemporal nerve. The presence of the latter and of the *great auricular nerve*, supplying the gland with sensation, within the unyielding parotid fascia accounts for the severity of this pain.

The **external carotid artery** lies under cover of the ramus of the jaw up to the junction of the middle and lower thirds of its posterior border where it enters the internal or deep surface of the parotid quite anteriorly. Thence it continues through the upper three fourths of the gland in a direction upward, outward and slightly backward to behind the neck of the condyle of the jaw, where it has become more super-

ficial and divides into its two terminal branches. These *branches*, together with the posterior auricular and sometimes the occipital, are within the parotid at their commencement. Within the gland the artery is *separated from the internal carotid*, and the accompanying internal jugular vein, vagus, glossopharyngeal, hypogastric and sympathetic nerves, by the styloid process and its muscles, the parotid fascia and a varying thickness of gland tissue.

It may be difficult at times to tell the *source of arterial hemorrhage* in a deep parotid wound. But in general, if the source of the bleeding can not be found and both ends tied, it is best to expose and tie the external carotid first and then if necessary the internal carotid, not the common carotid. It is evident from its relations that the *styloid process* is a most important *landmark* in extensive operations on the parotid for it indicates its inner boundary, the position of its prolongation toward the pharynx and of the deep vessels.

The **temporomaxillary vein** lies superficial to the artery and usually divides within the parotid into its *two divisions*, one of which continues downward to the lower border of the gland to become the *external jugular* while the other, passing downward and forward, joins the internal jugular. The number, size and deep situation of the *vessels* in the narrow and deep parotid region accounts for the *gravity of wounds* of this region when one of the vessels is injured.

From the *circumference* of the surface of the gland many of the contained *nerves and arteries* take their *exit*; posteriorly the posterior auricular artery, superiorly the auriculotemporal nerve and the superficial temporal artery, anteriorly the transverse facial artery and the branches of the facial nerve as well as Stenson's duct.

Both superficial to and within the substance of the gland are a number of **lymph nodes** which receive lymph from the temporal and frontal regions of the scalp, the outer part of the eyelid, the orbit, the cheek, the nasal fossa, the nasopharynx, the external auditory meatus and the intracranial parts. They empty into the deep and superficial cervical nodes. These lymph nodes when enlarged form one variety of parotid tumor. The sources from which they derive their lymph supply should be examined for the presence of lesions, in diagnosing between lymphatic enlargements and other parotid tumors. *Abscess* on the surface or within the gland may be due to an inflammation of these nodes. The deep nodes are found especially along the carotid artery.

**Tumors** of the parotid are not uncommon and mixed tumors, containing cartilaginous, myxomatous and fibrous portions, occur quite often among them. In addition there are *malignant tumors* or malignant degeneration of benign tumors. It is a striking fact that the *testis*, in which metastases after mumps are quite common, is also one of the few other soft parts where cartilage occurs in tumors. The *benign tumors* are often encapsulated and involve only a portion of the gland so that their extirpation may be readily accomplished and the *facial nerve*, perhaps somewhat displaced, may be *spared* in whole or in part. It has been much discussed whether the *entire gland* can be or should

be removed when involved in a new growth, especially a malignant one. The operation is difficult, but it certainly can and should be done if the tumor is confined within the capsule of the gland. It is to be expected that the *facial nerve* must be *sacrificed*, but the result of this is often not so distressing as might be expected. I have found the operation entirely feasible in a recent case of removal of the entire parotid involved in a recurrent endothelioma. The external carotid and external jugular are tied in the earlier stages of the operation for the bleeding is very free from the arterial branches, including the temporal, internal maxillary, posterior auricular, and transverse facial arteries and the branches supplying the gland. *Incisions* over the parotid for minor conditions should be transverse so as to avoid the branches of the facial nerve.

The upper and lower jaws are both susceptible to **phosphorus necrosis** among those who work with phosphorus, as in match factories, but it is almost confined to those with carious teeth. I have also seen it in an old colored man who took phosphorus internally for a long time to keep up his sexual vigor. There is usually an osteoplastic periostitis resulting in the production of osteophytes, which themselves are liable to necrose.

The upper jaw or **maxilla** is supported or buttressed *above and internally* by the articulation with the frontal and nasal bones, *above and externally* by the vertical portion of the malar, *behind* by the pterygoid process, *externally* by the zygomatic arch, *internally* by the articulation with the opposite maxilla in the hard palate. Thus supported it is not very often fractured but it may be by direct or indirect violence. In the latter manner the shock is usually transmitted through the lower jaw as in a fall or blow, more rarely through the head while the chin is fixed, sometimes through the malar bone which, on account of its density, is seldom fractured but may be driven into the upper jaw. Fracture by direct violence may be due to a direct injury over a circumscribed area or to the violent extraction of a tooth. The maxilla is partly protected from direct violence by the prominence of the nose internally and the malar bone externally. When the *wall of the antrum* is fractured it may be much depressed, depending upon the direction and degree of the force. Whether it is depressed or not *subcutaneous emphysema* may occur and is increased on blowing the nose. In other cases *pain* referred to the dental or infraorbital nerves may lead to the diagnosis; thus in one case my attention was first called to a fracture through the infraorbital margin and canal by pain in the nerve.

Although the maxilla is very *vascular*, yet its periosteum, like that of the skull, is not likely to form new bone so that there is no reproduction after necrosis. The infraorbital margin is the favorite seat of *tubercular periostitis* and *osteomyelitis* of the maxilla.

The fact that the maxilla is *connected* with the surrounding bony parts at *four points* is important to remember in its **excision**, which is undertaken in case of malignant tumors, etc. (1) The connection with

the *malar bone* is divided by a wire or chain saw passed through the fore part of the sphenomaxillary fissure after raising up the periosteum of the orbital floor. (2) The *nasal process*, together with the lachrymal bone and the orbital plate of the ethmoid, is divided by the bone forceps whose blades are introduced into the nasal fossa and the orbit below the *tendo oculi*. In some cases most of the orbital floor may be left, the section passing just behind or sometimes below the orbital margin. (3) The *hard palate*, by which the opposite maxilla and palate bones are connected together, is divided by a saw or bone forceps after extracting a central incisor and dividing and stripping up the muco-periosteum on its under surface. (4) Its connection behind with the *pterygoid process* and the intervening palate bone, as well as with muscular attachments (external pterygoid), are freed by twisting the bone, to *avoid* unnecessary injury to the branches of the *internal maxillary artery*. Before this last step in the removal of the jaw it is well to *cut* the *infraorbital nerve* at the back of its groove in the floor of the orbit and to divide the connection of the *soft palate* with the back of the hard palate on the affected side. The bony connections are divided in the order named.

To *expose* the maxilla for *excision* the soft parts are divided down to the bone along the lower margin of the orbit to the side of the nose, thence in the groove between the nose and the cheek and the nose and the lip to the ridge on the side of the filtrum of the lip and down this ridge through the lip. In this *incision* the following *nerves and vessels* are *cut* in the following order from above downwards ; the palpebral branches of the infraorbital vessels and nerve, angular artery and vein, lateralis nasi vessels, nasal branches of the infraorbital nerve and the superior coronary vessels. Several small branches of the facial nerve may also be cut. Notice that *no large vessels* are *divided* in the soft parts and the same may be said of the bone section, though the operation may appear bloody from the many small branches divided. The attachment of the lateral cartilages of the nose to the bone are divided, thus opening up the anterior nasal orifice. The *flap* is then *turned back*, keeping close to the bone if the soft parts are not involved and in any case taking care to *preserve* the *facial artery* and vein and to *avoid Stenson's duct*. The latter may be accomplished by remembering its course and dividing the mucous membrane close to the gums so as to avoid the orifice of the duct, 4 mm. above this point.

The division of the *mucous membrane* may be left toward the last to avoid the flow of blood into the mouth. In rare cases, but not as a rule, the muco-periosteum of the palate may be spared by dividing it close to the alveolar margin, stripping it up and subsequently suturing it to the mucosa of the cheek, thus roofing over the oral cavity. The *skin flap* is *well nourished* by the facial and transverse facial vessels and is supplied by the facial nerve. The *scar* is almost imperceptible in time. By stripping up the periosteum of the orbital floor the *contents of the orbit* are spared, but the origin of the inferior oblique muscle is detached. In dividing the nasal process of the maxilla and the

lachrymal bone the *lachrymal sac* or the *nasal duct* will be cut across. If the nasal process is removed high up the origin of the *tendo oculi* is included. In the last step of twisting off the maxilla the *descending palatine artery* and great palatine nerve are severed. In some cases where the tumor involves only a part of the maxilla, most commonly the alveolar process, the excision may be partial, sparing in such a case the orbital floor and margin.

Again *temporary resection* of the *maxilla* is practiced to gain access to the *nasopharynx* in order to remove polypi situated there; or to expose the orbit, sphenomaxillary or temporal fossæ in order to remove tumors or excise nerves situated in these parts. In temporary resection the *alveolar arch* and *palate* are left *undisturbed*, the section passing into the nose above them; the connection with the malar bone is severed and, after another horizontal section is made from the orbit to the nasal fossa, the bone flap is *turned inward* as on a hinge, breaking the nasal process, and is replaced at the end of the operation.

The **lower jaw or mandible** is more often fractured than any other bone of the face, in spite of its free mobility, the buffer-like interarticular cartilages and its horseshoe shape, which gives it increased elasticity. It may be broken by *direct or indirect violence*. In the latter case the pressure increases the curve until it *gives way*, usually at its *weakest point near the symphysis*. It is more often fractured by *direct violence* and in this case also most often *near the symphysis*. The *line of fracture* may be nearly vertical, especially when at or near the symphysis, or more oblique, in most cases of fracture further back.

The *displacement* depends upon the position and direction of the fracture and the direction of the force. In general the elevator muscles attached to the ramus draw the *posterior fragment* upward, forward and outward while at the same time the depressor muscles, digastric, mylohyoid and geniohyoid draw the *anterior fragment* backward, downward and inward. In case of a *fracture of the ramus* itself the muscles attached to it hold the fragments together. In *double fractures*, which are quite common, the intermediate fragment may be displaced downward and backward. The displacement in fractures of the body of the bone is usually plainly visible in the difference of *level of the teeth*.

Although, owing to the firm character and close attachment of the gums to the bone, fractures of the body of the lower jaw are almost always *compounded* in the mouth and are thus exposed to bacterial infection, these fractures generally do well if kept in good *position*. This we may accomplish by splinting the lower against the upper jaw by the pressure of bandages, preferably with an *interdental splint* intervening. A fracture posterior to the mental foramen may injure the *inferior dental nerve* so as to be very painful and sometimes to cause anaesthesia of the lower lip and chin, supplied by its mental branch. The nerve escapes injury more often than one would suppose and it has been in rare instances compressed later on by the callus.

*Speech* is interfered with on account of the attachment of the muscles of the tongue and the floor of the mouth to the jaw. If the attachment of the genioglossus is displaced backward in a fracture or is divided in excision of the jaw some trouble may be experienced from the *tongue falling backward* and blocking the pharynx. The *condyle* is occasionally broken on one or both sides by direct blows or blows on the chin, and I have seen an oblique fracture of the ramus running from behind downward and forward and separating the region of the *angle* from the rest of the bone. Fractures of the alveolar process are common in connection with pulling teeth.

The *lower* like the upper *jaw* may be the seat of *malignant tumors*, especially sarcoma, which as well as extensive necrosis may call for **excision** of half of the jaw, more or less. Excision of the entire jaw is rare. *Epublis*, usually a sarcoma of the alveolar process of the lower or upper jaw, may be excised from within the mouth, well within sound tissue. In excising *half of the mandible* an *incision* is made down to bone along its lower border, commencing a little beyond the median line. It is not necessary to extend it up the back of the ramus and if this is done it should not extend more than 2 cm. for fear of wounding the facial nerve or even Stenson's duct. Except in large tumors it is not necessary to incise vertically through the lower lip.

The horizontal *incision* divides the facial vessels at the antero-inferior angle of the masseter, also some branches of the facial and superficial cervical nerves. If the lip is incised in the median line the anastomoses between the inferior coronary, inferior labial and submental vessels of the two sides are divided. The bone is then freed of its muscular attachments, keeping close to the bone. Except when there is a malignant growth, which has reached to or developed from the surface, the jaw may often be excised *subperiosteally*, largely by blunt dissection. In this connection Tillaux has called attention to the importance and the feasibility of preserving the periosteum covering the angle and adjoining parts which connect together the attachments of the masseter and internal pterygoid muscles. The *entire jaw* has been reproduced after subperiosteal removal.

It is sometimes difficult even with much depression to free the attachment of the temporal muscle which, it should be remembered, is attached to the margins and the inner surface of the *coronoid process*. The tip of the latter is sometimes cut off with the bone forceps in place of detaching the muscle. As to the *condyle* it is best at the last to twist it off instead of cutting the capsule and the insertion of the external pterygoid, on account of the danger of wounding the internal maxillary artery as it winds around the neck of the condyle. The *inferior dental vessels and nerve* and their mylohyoid branches are of course divided close to the *inferior dental foramen*. In *large tumors* care should also be taken to *avoid* the salivary glands, the external carotid artery, the temporomaxillary vein and the lingual and auriculo-temporal nerves. *Cysts and tumors* of the jaws may also develop from the tooth germs. In a *central sarcoma* or other tumor *pain* from pres-

sure on the dental nerves may be one of the earliest symptoms noticed. *Congenitally*, and depending upon defective development of the first branchial arch, the jaw has in rare cases been cleft at the symphysis, incompletely formed or entirely absent.

**Temporomandibular Joint.**—The condyle can be seen and felt as a slight *projection* immediately in front of the tragus of the ear, from which point it can be seen and felt to move forward and downward onto the articular eminence when the mouth is widely opened. In *dislocation* the condyle passes forward and upward from the eminence into the zygomatic fossa. The *depression* which is seen and felt in place of the normal projection in front of the tragus is a valuable sign of dislocation, especially when it is unilateral. The *bony external auditory meatus* is immediately behind the joint and in falls or blows on the chin the condyle may be driven upward through the glenoid fossa fracturing the base of the skull or backward fracturing the anterior wall of the meatus. In the latter way only is a posterior dislocation possible. The *direction* of the fibers of the only strong ligament of the joint, the *external lateral*, is downward and backward so that it resists the backward movement of the condyle and thus protects the wall of the meatus from more frequent injury.

**Dislocation** of this joint is permitted in the *forward* directly only, with the above exception. It occurs only when the *mouth is widely open* and the condyle is on the *eminentia articularis* from which it is pulled forward by the external pterygoid in *violent yawning*, laughing or vomiting, in dentists' operations, and in the violent introduction into the mouth of large objects. When the *condyle* is pulled in front of the articular eminence it *glides upward* along the inclined surface in front of the eminence and is pulled up by the elevator muscles. The jaw however can not be closed but is *held widely open* and the fixity of this position and the difficulty of reduction is explained in different ways. (1) The *direction* of the fibers of the *external lateral ligament* is *reversed* in the new position of the condyle and the attempt to close the jaw now puts this ligament on the stretch. The same is true of an attempt to push the jaw backward, for it has to pass downward to pass beneath the articular eminence. A *downward* as well as *backward pressure* is therefore necessary in the *reduction* of the dislocation and this can be effected with the least tension of the external ligament if the jaw is at first kept widely open or even opened more widely. It is not true, however, as is sometimes stated, that the *external lateral ligament* is relaxed when the mouth is wide open but rather the reverse, for the ligament is tightened by depression of the jaw and by the downward gliding onto the articular eminence more than it is relaxed by the forward movement of the condyle.

(2) In the combined hinge and sliding movement of the jaw the condyle moves forward, the angle backward and the *axis of motion*, or the part which moves least, is about the center of the ramus, or at the inferior dental foramen. Hence the vessels and nerves which enter this foramen are not subject to traction and displacement as they other-

wise would be. The line of action of the masseter and internal pterygoid muscles normally passes upward and forward in front of this axis. When however the jaw is dislocated forward the line of action of these muscles is displaced somewhat backward with the angle, while the axis of motion is displaced in front of it. (Fig. 24.) Hence while normally the action of these muscles is to elevate the front of the jaw and depress the angle, in a dislocated jaw their action is to elevate the angle and depress the front of the jaw, *i. e.*, to open it. That the muscles are spasmically contracted, from their being injured or put on the stretch or from pressure or traction on their nerves can be readily felt. According to Tillaux a dislocation is produced when in a violent opening of the mouth the axis of motion is carried in front of the line of muscular action. In a dislocation the condyle may be said to be held by a balance of forces between the external lateral ligament

FIG. 24.

Figure to show the relation of the line of action of the masseter and internal pterygoid muscles to the axis of movement of the lower jaw in its normal position and in dislocation. The dotted line represents the position of the dislocated jaw. (TILLAUX.)

pulling upward and backward, and the muscles pulling upward and forward. (3) It is possible in rare cases, as in the specimen in the Musée Dupuytren, that the apex of an unusually long coronoid process may be caught against the malar bone and resist reduction.

In dislocation the fibrocartilage may pass forward with the condyle or it may remain behind in the glenoid fossa and in the latter case the anterior part of the capsule may be torn. The posterior part of the capsule is much stretched and often torn. The dislocation may occur on one or both sides.

The lower jaw is sometimes held *firml y closed*. This may be due to a tonic spasm of the muscles of mastication, a condition known as **trismus or lockjaw**. This may be an early symptom of *tetanus* or a *reflex symptom* due to the irritation of one of the sensory branches of the fifth nerve, especially those of the lower teeth. The *nerve to the muscles of mastication* is the only motor branch derived from the fifth nerve.

Again the *firm closure* of the jaw may be due to a *cicatricial contraction* following a *cancerum oris* or other large loss of substance of the cheek or to an *ankylosis* of the temporomandibular joint. In the latter case an excision of the neck of the condyle is done to secure a false joint.

**The two lips** unite laterally at the *commissures* to enclose a transverse aperture (*the buccal orifice*) popularly called the mouth, but the latter term should apply to the cavity to which the opening leads. The lips consist of the *following layers*: (1) Skin closely adherent to (2) a muscular layer (*orbicularis oris*), (3) labial mucous glands among which are the coronary vessels and (4) mucous membrane.

The **thick skin** joins the mucous membrane along the free border by an intervening "*vermilion border*," or dry mucous membrane, which is remarkable for its *sensitiveness* and the frequent occurrence of *epithelioma*, especially on the lower lip. This border on the upper lip presents a median tubercle, the remains of the free extremity of the frontonasal process. From this tubercle up to the *columna nasi* is a shallow groove, the *filtrum*, bounded by two low ridges along which vertical incisions are carried if it is desired to show as little scar as possible.

The **muscular fibers** run mostly parallel with the buccal orifice, hence *incisions* to open abscesses, etc., should be *horizontal*, for a vertical incision is followed by considerable retraction of the edges. Into the *orbicularis oris* are inserted most of the muscles of expression.

The **glandular layer** is formed of racemose glands resembling the salivary glands. It may hypertrophy as a whole, thickening the lip, or the individual glands may form retention cysts. On a vertical section of the lips this layer protrudes while the muscular layer retracts. The **coronary arteries** are embedded in this layer close beneath the mucosa and nearer the free than the attached margin of the lips, about one half inch from the former. *Bleeding* from them may be easily *prevented or stopped* by pressure of the fingers or a temporary ligature. In suturing vertical incisions of the lip, as in harelip operations, one suture should be passed behind both ends of the artery, between it and the mucosa, to check the hemorrhage. The coronary arteries can retract freely into the loose tissue in which they lie so that bleeding is often spontaneously arrested. As the superior coronary artery sends a branch to the *septum nasi*, *compression* of the artery may *check nose bleed*. The *vascularity* of the lips, from the coronary and other arteries, accounts for the frequent presence of *nævi* and other vascular tumors as well as for the ready *healing* of the many plastic operations performed to relieve deformities and fill the gaps left by the removal of

new-growths about the mouth. The success of these operations is also favored by the laxity and mobility of the tissues about the mouth. The vessels of the two sides of the lips *anastomose* freely, hence *both ends* of a divided vessel should be *tied*. The connection of the veins through the facial and ophthalmic, with the cavernous sinuses should be remembered in inflammatory conditions of the lips.

The **lymphatics** pass to the submaxillary and suprathyoid nodes so that these nodes may be involved and require removal in *epithelioma* of the lip. The **nerves** of the upper lip (infraorbital) come from the second division, those of the lower lip (inferior dental) from the third division of the fifth nerve. There are numerous end bulbs resembling tactile corpuscles in the sensitive vermillion border. Over the labial nerves a crop of herpes (*herpes labialis*) often appears.

The **mucous membrane**, reflected onto the gums above and below at the attached margin of the lips, presents on each lip a small median fold or *frenulum* of which the upper is the larger. In extensive *plastic operations*, as after the removal of a large epithelium of the lip, it is essential for a good and permanent result that the *flap* should be *lined by mucous membrane*, otherwise it becomes adherent to the jaw and immovable and does not oppose the dribbling of saliva. In case the new-growth is smaller a V-shaped incision with suture of the edges suffices.

**Development.**—In the foetus, near the end of the second week the buccal and nasal cavities are one, bounded above by the frontonasal process, laterally by the superior maxillary processes and below by the first visceral arch. These two cavities are separated by the median fusion of the frontonasal and superior maxillary processes to form the upper lip and palate, as well as the upper part of the face.

The *lower lip* is formed by the median fusion of the coverings of the lateral halves of the first visceral or mandibular arch. Failure of this fusion, resulting in a median cleft of the lower lip, is very rare and only a few instances of it are on record. The *upper lip* is formed by the fusion of the coverings of the two laterally placed superior maxillary processes and the median frontonasal process. Failure of this fusion on one or both sides of the frontonasal process causes **single or double harelip**. Hence this is *lateral and not median*; a median cleft, like that of the hare, being very rare and otherwise formed. Harelip is more often *single* and on the *left side* and is commoner in males. It may involve part of the lip only or extend up into the nostril. In the latter case it is often combined with a *cleft* of the *alveolar arch* or of the *palate* as well.

In **double harelip** the central insulated part of the lip often appears as a nodule attached to or suspended from the nose, for it protudes on the intermaxillary bone which projects forward at the end of the vomer. This condition is due to the fact that the intermaxillary bone, the *septum* of the nose and the central part of the lip are formed by the frontonasal process. In **single harelip**, or on one side of a double harelip, there may be a *projection* of the *alveolar arch* on the median

side of the cleft, making its closure more difficult, so that the projection should first be reduced.

According to Albrecht, the *cleft* is between the frontonasal and the lateral frontal processes, but its location is not always the same. Harelip is opposite the interval between the central and lateral incisors or between the latter and the canine tooth. The superior maxillary process, according to Albrecht, is only concerned in the oblique facial cleft which, according to him, is due to the non-union of the lateral frontal and superior maxillary processes.

The *cure* of harelip by *plastic operation* is very satisfactory. The two halves of the lip must first be freed from the maxilla, to which they are unusually adherent, the edges freshened in one of several ways and then sutured. *Transverse facial clefts*, due to failure of fusion of the mandibular arches and the superior maxillary process, commence at the corners of the mouth and cause an enlargement of the latter (*macrostoma*). The opposite condition, or *atresia* of the buccal orifice, occurs when the fusion exceeds the normal limits or it follows contraction due to pathological processes, such as burns, or faulty plastic operations. It may also be relieved by operation.

When the jaws are closed there exists between them and the cheeks and lips a space known as the *vestibule of the mouth*. The *circumference* of this space is *bounded* by the reflection of the mucous membrane from the gums to the cheeks and lips. Through this reflection we may *incise* to expose the infraorbital and mental nerves and to open the antrum, as described above. It is near this line of reflection that we find the *abscesses* which are developed from a fistulous tract leading from a diseased root of a tooth. Such an abscess may be seen, if within the vestibule, or felt if just beyond. At the back of the vestibule, behind the last molar, is a space usually large enough for the passage of a feeding tube in case of trismus; and in addition liquids can trickle through the interstices between the teeth. The *anterior border* of the *coronoid process* can be *felt* plainly at the back of the vestibule. In *dislocation* it is much more appreciable and its prominence may be an aid to diagnosis. In addition, as this border passes down onto the body of the jaw, external to the alveolar process, it forms a kind of *shelf* outside of the last molars on which we may make pressure with the thumbs in reducing a dislocation of the jaw and thus avoid the danger of being bitten when the jaws close with a snap on reduction. The *duct of Stenson* opens into the vestibule (see p. 87).

The *gums*, formed by the closely united *mucous membrane* and *periosteum* covering the alveolar processes, are dense, firm and vascular, though paler in color than the adjacent mucosa. As the periosteum of the gum is continuous with that lining the sockets of the teeth inflammation originating in the socket from a carious tooth, especially a single fanged tooth, may extend up and out of the socket beneath the periosteum and form a *subperiosteal alveolar abscess* or "gum-boil." The pain is considerable, as the pus is bound down by the

dense gums. A similar inflammation may burrow through the bony wall of the socket and appear beneath the gums a little further from the alveolar margin (see above). In either case the abscess may open or be opened here and go no further, or it may extend widely beneath the periosteum and cause a *necrosis of the jaw*. If the end of the root socket of a tooth is beyond the limit of the gums, or if the pus can gravitate beyond it, the abscess is likely to break through the cheek instead of through the gums. *Ulcerated teeth* are the *common cause of necrosis* of the jaws and should be suspected in case of swelling, abscess or fistula of the face and submaxillary region. A similar *inflammation* in the sockets of the *upper molars* may spread to the *antrum* and be the cause of an *empyema* there.

The gums covering the outer and inner surfaces of the alveolar process are continuous in the interstices between the teeth and are normally closely *adherent* to the *neck of the teeth*, thereby helping to hold them in so that when the gums are detached the teeth are more liable to become loose. From the gums are developed a class of *tumors* called *epulis* which may be a simple fibrous hypertrophy of the gums or a sarcoma developed from the periosteum. The latter form requires the removal of the adjacent portion of the alveolar process to avoid recurrence.

In *old age* as in *infancy* the gums cover the upper border of the jaw; in the former case they are very thick and hard, so as to allow a certain amount of mastication, in the latter case they become much inflamed and cause much irritation during the eruption of the teeth. In *mercurial poisoning* and in *scurvy* the gums are characteristically congested and spongy, so that they bleed readily and may become ulcerated. In *chronic lead-poisoning* a blue line of sulphide of lead may appear along the dental margins of the gums, due, it is said, to the action on the lead of hydrogen sulphide formed by the decomposition of food débris about the teeth, if the latter are not kept clean.

**The Teeth.**—It is impracticable to try to remember the time of eruption of each of the *twenty temporary* and *thirty-two permanent teeth*. The *order of appearance* is much more regular than the exact time, which is liable to much variation. The *temporary teeth* appear in the *following order*, lower central incisors, upper incisors, lower lateral incisors and the four anterior molars, the four canines and finally the four posterior molars. The *first dentition* usually *begins* in the seventh month and is *completed* at the age of 2 or  $2\frac{1}{2}$  years. The lower teeth appear before the upper. In rare instances a child is born with teeth. *Syphilitic children* are rather prone to early dentition and early decay of the teeth. Dentition is often delayed in *rickets* and still more so in *cretinism* and it may be said to go on in a manner corresponding to the ossification of the cranial bones.

In the *permanent set* a *similar order* is followed except that the first molars (*6-year molars*) are the first to appear, usually in the seventh year. The second molars (*12-year molars*) appear from the twelfth to the fifteenth year, the third molars, or wisdom teeth, from the seven-

teenth to the twenty-fifth year, or they may never appear, in which case they may lead to the formation of *cysts* of the jaw. It is to be noticed in both sets that the *canine teeth* appear after those on either side of them so that the anterior bicuspid may need to be pulled to make room for the canines.

Certain *tumors* (*odontomata*) of the jaws are developed from the teeth germs or growing teeth. They form tumors within the substance of the jaws of a fibrous, epithelial or bony structure according to the period of their development or the part of the tooth germ from which they spring. *Cysts of the jaws* have a similar origin from the dental sacs and retained teeth, as well as sometimes from the periosteum.

The *enamel* of the teeth is *developed* from the epithelium of the margin of the gums which, becoming thickened, dips into the substance of the gums as the "*dental shelf*" and forms as many epithelial caps or *enamel organs* as there are to be teeth in each set. Those of the *permanent set* lie *behind* those of the temporary set. From the dental shelf or enamel organs are formed the *epithelial odontomes*. The rest of the tooth grows up as a small papilla beneath the enamel organ and finally becomes capped by it.

The *incisor teeth* of the *permanent set* present certain *peculiarities* in many children having *hereditary syphilis*. The characteristic or "*test teeth*" of *Hutchinson* are the upper central incisors which present a single *crescentic notch* in the center of the free edge. These syphilitic teeth also are often short, thick and tapering.

**The Floor of the Mouth.**—The *mylohyoid* muscle forms the *diaphragm* or muscular floor of the mouth, separating the buccal cavity from the neck. All *tumors* or *abscesses* developed above this muscle project or point into the buccal cavity and may be operated upon by that route; while those developing below the muscle present in the neck and may best be reached by operation there.

**The tongue** occupies the greater part of the floor of the mouth. Between the interlacing *muscle fibers*, of which the tongue is composed, is a comparatively small amount of connective tissue. It is noteworthy that cellulitis or inflammation of this tissue (*glossitis*) is uncommon; but when it does occur the tongue may swell greatly so as to threaten asphyxia by pressing down the epiglottis. Owing to the firm texture of the tongue and its thick mucosa *abscess* in its substance feels like a solid tumor. *Foreign bodies* may easily become embedded in the tongue.

The tongue is not *attached* or anchored by ligaments but by *its extrinsic muscles*, to the mandible by the *genioglossi*, to the styloid process by the *styloglossi* and to the *hyoid bone*. Hence, in *anæsthesia*, when the *muscles become relaxed*, the tongue is liable to drop back by its own weight and press down the epiglottis so as to close the opening into the larynx. This tendency may be *diminished* by placing the patient's head on the side, so that gravity does not tend to force the tongue backward; or it may be *counteracted* by pulling the tongue forward either directly, by the tongue forceps, or indirectly, by protruding the

jaw, by pressing forward *behind the rami*, and thereby pulling the tongue through the genioglossi.

The tongue normally overhangs the entrance of the larynx, thereby hiding it, hence if the tongue is drawn too far forward it exposes the larynx and favors the passage of food or other fluids into it. Similarly when, in operations on the tongue or in excision of the fore part of the lower jaw, the genioglossi muscles are divided the tongue is liable to drop back if the patient lies upon his back. Hence precautions are taken to have the patient lie upon the side, to fasten the tongue forward by suturing its base to the mental region and to thread the tongue with a silk suture, whereby it may be pulled forward as occasion requires, until adhesions form which fasten it in position.

FIG. 25.

Under surface of tongue and the sublingual space, showing openings of salivary ducts. The mucosa of the left side is partly removed, and shows the ranine artery, the lingual nerve, and the gland of Blandin. (GERRISH, after TESTUT.)

The tongue is also connected by mucosa with the alveolar arch and by folds of mucous membrane with the epiglottis, the soft palate (enclosing the palatoglossus muscle) and the back of the symphysis of the jaw. The latter is a median fold known as the *frænum linguæ* which normally ends some distance short of the tip of the tongue. In rare instances this *frænum* extends to the tip or is abnormally short so as to restrict the movements of the tongue. This condition of "*tongue-tie*" may prevent the infant from sucking well or, later in life, interfere with articulation and necessitate *division* of the *frænum*. This may be done after lifting up the tongue by the fingers or the back end of a

grooved director, which is made for the purpose. In such cases the *free edge* of the frenum should be *divided close to the jaw* so as to avoid the ranine veins on the under surface of the tongue, and the frenum may be torn loose as much as required. If there is any bleeding in such cases it is encouraged and not checked by the infant's nursing.

The **ranine veins** just mentioned are plainly seen beneath the mucosa of the under surface of the tongue, less than half an inch from and on either side of the frenum. The **ranine arteries** lie a little more laterally and more deeply placed, beneath fringes of mucous membrane which converge toward the tip.

*Surface of the Tongue.*—It is the bright red color of the fungiform papillæ, scattered along the sides and tips of the tongue, contrasted with the coating of the rest of the tongue, which produces the so-called "strawberry tongue" of scarlet fever. The *coating* of the tongue is composed of a mixture of desquamated epithelium, food débris and bacteria. Behind the circumvallate papillæ there is much *lymphoid tissue* in the mucous membrane. This is collected into rounded masses which are sometimes hypertrophied to form an irregular nodular mass known as the **lingual tonsil**, which may require removal on account of its impairing the movements of the glottis. The *foramen cæcum* at the apex of the circumvallate papillæ represents the upper end of the lingual or **thyroglossal duct**, in connection with the lower end of which the thyroid gland is developed. From or contiguous to this duct there occasionally develops a *tumor* of the base of the tongue resembling the thyroid gland in structure. *Mucous cysts* are sometimes developed from the mucous glands which abound over the posterior third of the tongue.

The *surface epithelium*, owing to chronic irritation or inflammation, may become thickened in the form of dense opaque plaques. This condition, variously known as *psoriasis* or *ichthyosis linguae*, *leucoma* and *smoker's patch*, is important as it may develop into **epithelioma**, which is common in the tongue, especially on the side of the anterior half. *Tubercular* or *syphilitic ulcers*, which also occur on the tongue, may sometimes be mistaken for it.

The **treatment of epithelioma** is **excision of the tongue** by one of the various methods employed, through the mouth or from beneath the jaw and with or without previous ligature of the lingual arteries in the neck (see p. 125). In operating through the mouth more room is obtained by stretching the mouth, splitting the cheek or dividing the lip and jaw.

*Hemorrhage* is the chief obstacle in operating through the mouth. It is not the amount but the locality of the bleeding and the danger of its running back into the larynx and trachea that concerns us. Hence the value of *preliminary ligature* of the *linguals* in the neck. Some bleeding still occurs on the stump, especially if the tongue is divided far back. This comes from the *dorsalis linguae* branches, which are not shut off by the ligature, and from small anastomos-

ing vessels of the ascending pharyngeal and the tonsillar branches of the facial arteries. Bleeding from the stump can be arrested, and the stump brought well up to view, by pressing up the floor of the mouth by the fingers applied between the jaw and the hyoid bone. If the *operation* is limited to *one side* it is only necessary to ligate the lingual on that side, for there is but little anastomosis across the rather incomplete median fibrous septum of the tongue. The two ranine arteries *anastomose* by a small loop near the tip of the tongue, otherwise only by capillary branches, except in the rare cases where the principal part of both linguals are given off from one side. In the latter case ligature of the small vessel on the other side would not prevent copious bleeding on that side.

The following *structures* are *divided* in an excision of the entire tongue : the mucous membrane connecting the tongue with the jaw the epiglottis and the soft palate ; the genio-, hyo-, stylo-, and palatoglossi and the lingualis muscles ; the lingual, hypoglossal and glosso-pharyngeal nerves and the lingual vessels and their anastomoses (see above). In **Kocher's operation** a *flap* is turned up *below the jaw*, the muscular diaphragm of the mouth (mylohyoid) divided and the mouth then entered by dividing the mucosa along its attachments to the gums. Through the *same incision* any infected *submaxillary lymph nodes* may be removed, the *lingual artery* tied and excellent *drainage* provided to guard against septic aspiration pneumonia, a not infrequent cause of death in such operations. **Wounds** of the tongue are not uncommon and may require suture. I have seen a case where a child bit her tongue half through and a similar accident had occurred in two previous generations of the family.

As a consequence of the *vascularity* of the tongue it is often the seat of nævoid growths. The **lingual arteries** (averaging 3 mm. in caliber) pass upward and forward to the base of the tongue beneath the *hyoglossus* muscle, in front of which they run forward as the ranine arteries near the under surface of the tongue. They are often brittle, especially at the age when cancer is prevalent. *Cancer* tends to extend toward the best blood supply, hence lingual cancer tends to spread downward toward the root of the tongue, which is also the course of the lymphatics. The **lymphatics** of the tongue are large, numerous and important in connection with the nodular infection which occurs early in lingual cancer. The lymphatics of the *fore part* of the tongue enter the submaxillary nodes ; those of the *back part* enter some small lingual nodes on the *hypoglossus* muscle and thence pass to the deep cervical nodes. The lymphatics for the most part follow the blood vessels of the tongue. The enlargement of the tongue in the strange congenital condition known as **macroglossia** is due principally to a great dilatation of the lymph channels (*lymphangioma*) and to an increase of the lymph tissue throughout the tongue. In some cases it reaches a prodigious size, filling and projecting far out of the mouth and deforming the teeth and alveolar arches by pressing them forward. The base of the tongue is the part most affected. Excision by a wedge-shaped incision or the use of the cautery sometimes gives a good result.

**Nerves of the Tongue.**—The *hypoglossal* supplies the *muscles* of the tongue, though the *chorda tympani* may carry some motor fibers from the *facial*. The *chorda tympani*, carrying fibers from the *glossopharyngeal* nucleus, supplies taste fibers to the anterior two thirds of the tongue; the *glossopharyngeal* nerve supplies taste and sensory fibers to its posterior third. The *lingual* or *gustatory* nerve supplies sensation to the anterior two thirds of the tongue, in which the *sense of touch* is more *acute* than in any other part of the body and is used by dealers in precious stones when the eye alone cannot be trusted. This nerve is not infrequently affected by *neuralgia* or responsible for *reflex symptoms* in painful affections of the tongue, which are most common in the anterior two thirds of the organ. Neuralgia of this nerve in cancer of the tongue is sometimes so severe as to demand its *division or excision*. By pulling the tongue forward and to the opposite side the nerve may be made *prominent* by its elevating a *ridge* of mucous membrane on the floor of the mouth, between the tongue and the alveolar arch. The nerve may be excised after *dividing* the mucous membrane *along this ridge*, except in cases where the tongue is much enlarged and fixed by cancer. This is better than merely *cutting* the nerve, as may be done by *Moore's method*, about half an inch from the last molar tooth at the point where it crosses the line from that tooth to the angle of the jaw, the knife being entered three quarters of an inch behind and below the tooth down to bone and the incision carried towards the tooth.

In painful affections of the fore part of the tongue the *pain* is often referred to other branches of the third division of the fifth nerve, producing pain in the auditory meatus or a spasmotic contraction of the muscles of mastication. After the lingual nerve has passed forward from between the ramus and the internal pterygoid muscle it runs beneath the mucous membrane, 5 mm. from its reflection from the side of the tongue and then beneath the *sublingual gland*, with Wharton's duct. It can be readily *felt* by the finger pressed against the inner surface of the jaw in a direction downward and backward from the last molar tooth. Branches of the *superior laryngeal nerve* reach the root of the tongue near the epiglottis.

The part of the *floor of the mouth* between the tongue and the alveolar arch is covered by mucous membrane, reflected from the tongue to the gums, and is divided into two symmetrical halves by the *frænum* of the tongue. On either side of the latter are two well-marked *ridges* directed backward and outward, due to the presence of the *sublingual gland*. Along these ridges the ten to twenty *ducts* of the gland open and at the anterior ends of the ridges, on either side of the *frænum*, we notice the *papillæ* on which are the *orifices of Wharton's duct*. The *duct of Bartholin*, from a group of lobes of the sublingual gland, opens with or near Wharton's duct.

Wharton's duct passes obliquely forward and inward for 5 cm. from the deep lobe of the submaxillary gland, near the posterior border of the mylohyoid. It accompanies the *lingual nerve*, crossing above the

latter, which inclines inward to the tongue, and it lies beneath and behind, or internal to, the sublingual gland. Its walls are thin but *not distensible* so that when it becomes *blocked* by an impacted calculus the *pain from tension* is intense as it cannot become rapidly or largely dilated to form a cystic tumor.

Such a cystic tumor is known as *ranula*, a term applied to cysts of varied origin filled with mucous contents and situated under the tongue or in the floor of the mouth. Typical ranula is a *retention cyst* of the mucous glands; according to Recklinghausen most frequently of those that lie beneath the tip of the tongue. Other cysts in this situation are classed as ranula, including retention cysts of the sublingual gland ducts or of Wharton's duct.

The presence of *Fleischmann's sublingual bursa* is denied by most authorities, but according to Tillaux it is the seat of the acute or rapidly formed ranula, which sometimes occurs. Tillaux describes it as follows. It is triangular in form, situated between the genioglossus muscle and the mucous membrane which is reflected from beneath the front and sides of the tongue to the floor of the mouth. Its apex lies at the end of the frænum on the under surface of the tongue and its base at the sublingual gland, which separates the mucosa from the genioglossus muscle. It is constricted in its center by the frænum and reaches back on either side to the first or second molar tooth. *Incision* alone will not cure a ranula, for after the incision heals the cyst refills. Its *lining membrane* must be *dissected out* as far as possible and the edges of what is left sutured to the opening in the mucous membrane.

*Congenital dermoid or branchiogenic cysts* in the floor of the mouth, between the tongue and the lower jaw, may resemble ranula. They are due to the imperfect closure of the first branchial cleft or arch. *Cysts or solid tumors* deeply seated in the tongue or in the vicinity of the hyoid bone may develop from the *thyroglossal duct*, leading from the foramen cæcum. In this manner probably some of the deep-seated forms of cancer and cancerous cysts of the neck are formed.

When the mouth is widely opened the *pterygomaxillary ligament* can be readily *felt* beneath the mucous membrane and can be *seen* as a prominent fold running obliquely downward behind the last molar teeth. The loose connective tissue in the floor of the mouth between the mylohyoid muscle and the mucous membrane, together with that in the submaxillary region, is involved in the septic inflammation known as *Ludwig's angina*.

**The Palate.**—The hard palate separates the mouth from the nose, hence when it is cleft these two cavities communicate. Its *form* is determined by that of the horseshoe-shaped alveolar arch which borders it. Normally the greatest *width* about equals its length, but this relation varies widely. Normally it presents a *flat arch*, abnormally a high and narrow one. The latter form is said to be common in congenital idiots and often occurs in the two halves of a cleft palate, especially in complete clefts. This is a fact of importance in the

closure of the cleft, for in such cases the flaps, when brought down to a more horizontal position, are ample to meet and be sutured in the median line. These *flaps* consist of the entire soft parts which cover the bony framework and are composed of a firm pale mucosa fused with the periosteum so that they can not be separated. This dense, tough *muco-periosteum* is thickened by the many *glands* contained between its two layers except in the median line. Posterior to the anterior palatine foramen a median raphe indicates the formation of the palate from two lateral halves).

The muco-periosteum is supplied principally by the **posterior palatine artery** which lies near its deep surface and passes forward, at the junction of the palate and the alveolar process, from the lower opening of the posterior palatine canal, internal to the last molar tooth. The two *principal dangers* of operations for the closure of a cleft of the hard palate are *hemorrhage and gangrene* of the flaps, both due to a division of the posterior palatine artery or its branches which pass inward to supply the muco-periosteum. Hence this division should be avoided and the *artery* and its branches *preserved* in the flap for its nourishment by making the *lateral incision*, bordering the flap, along the base of the alveolar process, outside the course of the artery. The *nerves* come from Meckel's ganglion.

**The soft palate** is of about the same *length* as the hard palate but it is *broader* than it is long, and about one quarter of an inch thick. Its *sides* are merged into the pharyngeal wall. The **anterior third** of the soft palate contains the **palate aponeurosis** which is always *firm and tense* so that, as it is continuous in position and direction with the hard palate, it is often hard to distinguish it from the latter by the touch, as in passing a Eustachian catheter (see p. 58). The aponeurotic portion does not share in the movements of the posterior or muscular portion of the soft palate. The *tendon* of the *tensor palati* muscle is connected with this aponeurosis which is already tense and can scarcely be made much more so. Indeed it is probable that the *principal action* of this muscle, certainly of those fibers attached to the fibrous portion of the Eustachian tube, is to open that tube. Such an opening occurs whenever the palate is raised, as in swallowing, and on this fact depends the Pollitzer method of inflating the middle ear (see p. 57).

The *levator palati* and *azygos uvulae* muscles were formerly thought to be supplied by the facial nerve, through the great superficial petrosal and Meckel's ganglion, and hence to be affected by paralysis of the facial nerve when the lesion is mesial to the geniculate ganglion. It is questionable whether this is the source of their nerve supply which is now traced through the pharyngeal plexus from the *spinal accessory nerve*. These two muscles are embraced in the palate by the two heads or layers of the *palatopharyngeus*. The fibers of the *palatoglossus* form the most inferior layer of those which make up the substance of the soft palate.

All the muscles named, except the *azygos uvulae*, join those of the opposite side in the median line and hence by their *contraction* tend to

widen a cleft of the palate or *pull apart the sutures* introduced to close it. According to some the levator and tensor palati are the chief agents drawing asunder the sutured cleft. To prevent this interference with the success of the operation many resort to free antero-posterior *incisions* through the palate along the side of each half, to divide the muscles. In place of this a *tenotomy* of one or more muscles, especially the levator palati and palatopharyngeus, has been employed by others. Billroth *broke off* the *hamular process* and displaced it inward together with the tensor palati tendon which winds around it, in order to relax the latter, with good results. The hamular process can be felt to the inner side and behind the last upper molar tooth. Wolff thinks the soft palate is best relaxed by separating the muco-periosteum from the bony hard palate as in operations to close clefts of the latter. In any case the aponeurosis must be freed from its attachment to the posterior border of the bony hard palate to allow the anterior part of the soft palate to come together readily.

The **posterior two thirds** of the soft palate, the portion behind its aponeurosis, forms the **velum pendulum palati** proper or the movable curtain which in breathing through the nose hangs down in the isthmus of the fauces and shuts off the mouth from the pharynx, and in deglutition or breathing through the mouth is raised to a horizontal position to shut off the buccal portion of the pharynx from the nasopharynx, to prevent food entering the latter in swallowing. Hence in *paralysis* of the palate, as sometimes occurs after diphtheria and from other causes, the palate can not be raised, the nasopharynx is not shut off and fluids are liable to regurgitate through the nose. The *elevation* of the palate during breathing through the mouth is taken advantage of in one form of nasal irrigation (see p. 80). When the palate is elevated it is enabled to shut off the buccal from the nasal portion of the pharynx by the contraction of the *superior constrictor muscle* which narrows this part of the pharynx and brings forward its posterior wall.

The azygos uvulae passes into the **uvula** and by its contraction shortens and raises it. *Elongation* of the uvula is largely due to hypertrophy of the part near the tip, beyond the muscle. When elongated it may touch the base of the tongue or produce coughing in the supine position by irritating the back wall of the pharynx. It may be readily snipped off if necessary. From the base of the uvula two folds of mucous membrane pass off on either side in an outward and downward direction, the *anterior and posterior pillars of the fauces*. The *anterior folds* cover the palatoglossi and incline forward. The space between them forms the **isthmus of the fauces**, the opening between the mouth and the pharynx, and is *bounded* by the tongue below and by the palate above. In deglutition, after the food is passed into the pharynx, the isthmus is closed by the contraction and approximation of its pillars and the elevation of the back of the tongue to the palate, to shut off the mouth from the pharynx. The *posterior folds* cover the palatopharyngei and incline somewhat backward. As the latter approach nearer to one another than the anterior pillars they

are readily seen behind them. Between the two pillars of each side lie the tonsils (see p. 111).

The **blood supply** of the soft palate is derived from the ascending palatine branch of the facial, the palatine branch of the ascending pharyngeal artery and the descending palatine branch of the internal maxillary. The **lymphatics** of the palate enter the internal maxillary or deep facial nodes, on the side of the superior constrictor just behind the pterygomaxillary ligament, and thence pass to the deep cervical nodes. The **sensory nerves** come from Meckel's ganglion and the glossopharyngeal. The latter nerve probably supplies the scattered taste buds found on the under surface of the palate. The terms **palatable**, to tickle the palate, etc., are not without physiological foundation in fact, though the tongue is the principal organ of taste.

**Development** (see also p. 99).—The palate is formed by the junction in the middle line of the palatal processes of the superior maxillary processes which grow backward and inward to separate the mouth from the nose. This union begins in front about the eighth week of foetal life and is completed posteriorly in the ninth and tenth weeks. Throughout the hard palate this line of union is joined from above by the frontonasal process, forming the septum of the nose, to the lower and anterior angle of which are attached the intermaxillary bones. These bones join the palatal processes of the maxillæ along suture lines passing forward and outward from the anterior palatine foramen to the interspace between the canine and lateral incisors of each side, so that they contain the four incisor teeth.

**Congenital cleft palate** is an error of development, a failure of fusion of the parts of which the palate is formed. In the *soft palate* the *cleft* is *median and single*; in the *hard palate*, as far forward as the anterior palatine foramen, it is nearly or quite median in position but is called *unilateral* or *bilateral* according as one or both palatal processes fail to join the vomer, which is formed by the median frontonasal process. If the cleft is unilateral it communicates with the nasal fossa of one side, if bilateral with both nasal fossæ and the free border of the vomer appears in or above the cleft. In one case I observed entire absence of the nasal septum, which occurs occasionally. *In front of the anterior palatine foramen the cleft in extending through the alveolar border is always unilateral or bilateral, never median.* If the cleft is bilateral the *intermaxillary bones* are entirely separate from the maxillæ and, supported on the end of the nasal septum, they often protrude forward and appear to be suspended from the end of or beneath the nose. Such forms are usually accompanied by a double harelip; the unilateral cleft of the alveolar process is as a rule associated with a single harelip, occasionally with a double one. In unilateral clefts the alveolar process of the intermaxillary bones may be on a line with the alveolar process across the cleft or it may project in front of it.

According to Kölliker and others, the cleft in the lip and alveolar process is between the frontonasal process and the superior maxillary process, *i. e.*, between the intermaxillary bones and the maxilla or

## PLATE VII.

FIG. 26.

Hard palate, showing the course of the arteries and of the lateral clefts. (Modified from Merkel.)

FIG. 27.

Horizontal section through the commissure of the lips and the tonsils. The section passes through the odontoid process and shows the pharyngo-maxillary space. (Merkel.)

between the lateral incisor and canine teeth. But Albrecht regards it as between the frontonasal and the lateral frontal processes. He assumes four intermaxillary bones, two on either side, and holds that the cleft is between the two of either or both sides, that is between the central and lateral incisors. His views have been largely confirmed by others. Both views are probably correct and the position of the clefts is not always constant. There are clefts between the lateral incisor and canine teeth, others between the lateral and central incisors, but more often the lateral incisor is wanting, which was formerly explained by saying that it was "lost in the cleft." In bilateral clefts through the alveolar process the protruded intermaxillary bones as a rule contain the germs of the central incisors only.

Cleft palate *varies* greatly in *extent*. Rarely it may involve the uvula only or merely the middle of the soft palate. A cleft of the soft palate often exists without any in the hard palate, or at most only in the posterior part of it; but clefts of the hard palate rarely occur without one in the soft palate. In rare cases the intermaxillary bones may be entirely absent and the coexisting double harelip appears as a large median gap.

Where there does not appear to be enough tissue to fill the gap of a cleft palate I have tried with excellent results the plan of chiselling through the palate processes along the inner border of the alveolar process, crowding inward the former, packing the gap so formed to keep the palate processes in their new position and after six or eight weeks completing the operation in the usual way.

The usual operation consists in broadly freshening both edges, dissecting up a flap of muco-periosteum on each side as far as the alveolar process, where it is limited by an incision along the base of the process (p. 108), and then bringing together and suturing the edges. It seems better to treat some bad clefts of the palate by an obturator fastened to the six-year molars. Such obturators, if well made, give an excellent functional result as far as speech and swallowing are concerned. Infants with cleft palate can usually nurse from a bottle if a large nipple is used which fills up the cleft. But later on articulation is very imperfect and the voice very nasal in tone.

The tonsils are lymphoid masses situated in the triangular recesses between the pillars of the fauces and the base of the tongue. The floor of this recess is formed by the pharyngeal aponeurosis and the superior constrictor muscle, on which each tonsil rests and by which it is separated from the pharyngomaxillary space. The latter lies between the lateral wall of the pharynx internally, the internal pterygoïd muscle externally and the upper cervical vertebrae posteriorly and contains fat and loose cellular tissue. Zuckerkandl showed that it was divided by the styloglossus and stylopharyngeus muscles into an anterior chamber, contiguous to the tonsil, and a posterior chamber containing in its hindermost part the internal carotid artery the internal jugular vein and their accompanying nerves. (Fig. 27.)

**Quinsy**, which is a *peritonsillitis* or an inflammation around the tonsil, is confined in most cases to the *anterior chamber* of this space and only rarely extends to the posterior chamber, in which case the internal carotid might possibly become eroded as reported in a few cases. The peritonsillar inflammation in the anterior chamber meets no obstacle in extending outward as far as the internal pterygoid muscle, but then further swelling projects inward toward the mouth in the line of least resistance.

A quinsy is *usually opened* through the soft palate just above the tonsil and the **wounding of the internal carotid** is out of the question for in the *adult* it lies 3 cm. behind this point in the normal state and probably twice as far when the parts are bulged forward by the inflammation. In *children* the distance is relatively even greater, though of course actually somewhat less. As the internal carotid is at least 1.5 to 2 cm. behind the tonsil there is even less danger of its being wounded in *tonsillotomy* for no puncture is then made. A wound of the artery has probably never occurred from tonsillotomy or opening a peritonsillar abscess, though several cases are recorded where the artery has become eroded in a peritonsillar inflammation. It is in operations on the lateral aspect of the pharynx that the internal carotid is in danger of being wounded.

The **external carotid artery**, 2 cm. from the lateral periphery of the tonsil, is still more out of the way, lying external to the muscles arising from the styloid process. The *ascending pharyngeal artery* is nearer the tonsil than the internal carotid, and gives a branch to it, but lies behind it in the pharyngomaxillary space and its main trunk is not exposed to injury in tonsillotomy. In one of the very few cases where fatal bleeding followed this operation the *tonsillar branch of the facial* was proved to be the source of hemorrhage. *Bleeding from the ascending pharyngeal artery* has proved fatal in a case reported by Mr. Morrant Baker, but it did not follow tonsillotomy but a wound due to a pipe stem driven through the tonsil. According to Merkel the *source of severe arterial hemorrhage* after tonsillotomy, etc., is in most cases the *facial artery* which, as it passes between the digastric and styloglossus muscles, may take a sharp S-shaped bend, which comes very close to the lateral surface of the tonsil.

The **position** of the tonsil corresponds superficially to the angle of the jaw but, owing to the intervening structures, enlargement of the tonsil other than malignant cannot be felt externally. What is felt and mistaken for the tonsil is an enlargement of the lymph nodes here which regularly accompany affections of the tonsil. Enlarged or *hypertrophied tonsils project* in the line of least resistance toward the median line where they may even meet and cause difficulty in swallowing. As the projecting mass of hypertrophied tonsils also narrows the pharyngeal passageway between the nose and the larynx the subject of such hypertrophy sleeps with the mouth open, to get more air, and usually snores. The throat therefore becomes dry and inflamed. In such cases the chest is badly developed, from insufficient supply of air, and

becomes pigeon-breasted if the subject has rickets. The nose is also small and flattened, as little air passes through it, and the voice is thick.

As the *soft palate* intervenes between the tonsil and the Eustachian tube the deafness complained of in such cases is not due to direct pressure, which is anatomically impossible, but to a *coexisting hypertrophy* of the adenoid tissue about and within the Eustachian tube. It is possible, however, that the hypertrophied tonsil by pressing up the soft palate may relax the tensor tympani muscle and thus hinder its opening the tube.

In the inflammation known as *follicular tonsillitis* the openings of the twelve or fifteen *crypts* on the free internal surface of the tonsil are filled with a yellowish-white deposit composed of desquamated epithelium, leucocytes, bacteria, etc. The decomposition of retained epithelial structures and food débris within the crypts of an enlarged tonsil may give rise to foul breath and to the repeated attacks of inflammation to which such tonsils are liable. The attachment of the tonsil to the muscles of the pharynx renders *deglutition painful* in acute inflammations of the tonsil because of the movements conveyed to the latter by the movements of the pharynx. Thus the superior constrictor moves it inward and the stylopharyngeus outward. The action of the latter in drawing the tonsil outward, combined with a prominent anterior faucial pillar may make it difficult to reach the tonsil with the *tonsillotome*. The latter should be introduced backward and slightly downward, for this is the direction of the *long axis* of the tonsil, which normally measures about one inch. Its postero-inferior end is sometimes hard to inspect.

Although the *blood supply* is from multiple sources the uninflamed tonsil is not very vascular so that it often bleeds but little on removal, but it may give rise to troublesome hemorrhage if removed when inflamed. The *arterial supply* comes from the tonsillar and ascending palatine branches of the facial, the descending palatine branch of the internal maxillary, the dorsalis lingue branch of the lingual and branches of the ascending pharyngeal. The *veins* form the tonsillar plexus on the outer side of the gland, which joins the pharyngeal plexus. The *lymphatics* of the tonsil enter the submaxillary nodes near the angle of the jaw, which are usually involved in affections of the tonsil and may be readily felt. The *nerves* come from Meckel's ganglion and the glossopharyngeal nerve. The latter as it winds around the palatopharyngeus is in such close relation to the tonsil as to be in some danger of injury in operations on or about the tonsil.

The tonsil is not infrequently the seat of *malignant new-growths*, sarcoma and epithelioma, on account of which it is removed with a wide margin of healthy tissue, either through the mouth, after splitting the cheek or dividing the jaw, or through the neck by a lateral pharyngotomy.

The **pharynx** extends from the basilar process of the occipital bone to the lower part of the cricoid cartilage, which is opposite the sixth

cervical vertebra, when the neck is neither flexed nor extended. It is  $4\frac{1}{2}$  inches *long*, much *wider* transversely than antero-posteriorly, widest opposite the hyoid bone (about  $1\frac{3}{4}$  inches) and *narrowest* (14 mm.) at the *lower end* where it is continuous with the oesophagus. Hence **foreign bodies** which reach the pharynx are most likely to be arrested at the latter point which is a little beyond the reach of the finger, for it measures *six inches from the incisor teeth*. The latter measurement should be remembered in passing oesophageal bougies to determine the position of a stricture, and it should be added to the length of the oesophagus ( $9\frac{1}{2}$  inches) to determine the distance from the teeth to the stomach.

The variety of foreign bodies reported as arrested in the pharynx is very great. Perhaps the most common are large masses of food swallowed glutonously, a frequent occurrence among the insane. Treves cites a case reported by Dr. Geoghegan where a tooth plate containing five teeth and surrounding five others was lodged in the pharynx for five months and caused trouble which was first supposed to be cancerous. Stones, coins, etc., are also arrested here and strangest of all, live cat fish are said to have jumped into the mouths of bathers in India and to have become impacted in the fauces. When the foreign body is a large one it may block the laryngeal opening and thereby cause suffocation. As *corrosive fluids* pass the narrowest point more slowly than the wider parts the corrosive action is more intense and the resulting cicatricial contraction more marked at the lower end of the pharynx than it is above.

The pharynx is *complete behind* and at the sides, where its musculo-membranous walls separate it from the surrounding parts. It is *incomplete in front* where it presents the *openings* of the posterior nares above, the faacial opening into the mouth below and still lower the upper orifice of the larynx. The *front* of the pharynx is held wide *open* by its attachment to the following fixed points, the internal pterygoid plate, mandible, hyoid bone and thyroid and cricoid cartilages.

**Relations of the Pharynx.**—The *posterior wall* of the pharynx is in front of the bodies of the upper five *cervical vertebrae*. The anterior arch of the *atlas* is on a *level with the palate*, and behind the mouth one can palpate the anterior surface of the bodies of the second and third cervical vertebrae, and in this way determine the existence of a *fracture or dislocation* of these vertebrae. Owing to their distance from the incisor teeth it is difficult to satisfactorily palpate the fourth and fifth cervical vertebrae. Necrosed portions of the upper cervical vertebrae have been discharged through the mouth.

In caries of the upper cervical vertebrae, which is most common in children, a *retro-pharyngeal abscess* may form in the loose tissue separating the posterior pharyngeal wall from the prevertebral fascia. A *lymph node* situated in this loose tissue opposite the axis receives lymph vessels from the hind part of the nasal cavity, the roof of the pharynx and the prevertebral muscles, and may also be the starting point of such an abscess. These abscesses may push forward the posterior

pharyngeal wall so as to depress the soft palate, or, if they extend further downward, they may cause dyspnoea by obstructing the opening into the larynx. They may open or be *opened* through the mouth or on either side of the sternomastoid after passing behind the great vessels and the parotid gland. If they discharge spontaneously into the pharynx during sleep the pus may be inspired and cause suffocation or set up a septic pneumonia. Abscess in this *loose retropharyngeal tissue* may descend along the oesophagus into the posterior mediastinum even to the diaphragm. This loose tissue serves the purpose of a serous cavity and allows the free movements of the pharynx.

FIG. 28.

Sagittal section of the pharynx, etc. (ZUCKERKANDL.)

The lateral walls of the pharynx are in close relation with the *internal carotid* arteries and their accompanying nerves (ninth, tenth and eleventh and sympathetic nerves) so that the pulsations of the artery may be felt through the pharyngeal wall and the artery may be wounded by foreign bodies thrust through the wall. The internal jugular vein is less exposed to injury from such causes, as it is more laterally placed. The *styloid process* and its muscles, the inner end of the *parotid gland* and the upper end of the *thyroid gland* are also in relation with the lateral walls of the pharynx. If *epithelioma* involves

a part of the pharynx, as occasionally happens, with or without invasion of the tonsil, it may be reached through an *incision* on the side of the neck. In such cases it is well to tie the external carotid, and, in order to reach the upper end of the pharynx, a division or temporary resection of the jaw may be made. The *lower end* of the pharynx may also be reached by *subhyoid pharyngotomy* through the thyrohyoid membrane, an operation which also exposes the portion of the larynx above the glottis.

The **nasopharynx**, or the upper part of the pharynx which is above the level of the palate and behind the posterior nares, is entirely *respiratory* in function. Accordingly its epithelium is *ciliated* and it is shut off from the lower or buccal portion, during the act of swallowing, by the elevation of the soft palate. The *superior constrictor* does not reach to its upper end at the sides as the constriction of this part serves no purpose. The space above the curved upper border of the superior constrictor, the *sinus of Morgagni*, is occupied by the thickened upper end of the pharyngeal aponeurosis, which lies internal to the constrictor muscles. Through this space pass the Eustachian tube and the levator palati muscle. In Politzer's method of inflating the middle ear the nasopharynx is shut off from the parts below by the act of swallowing, in which the palate is raised, so that the air forced into the nose finds no exit except through the Eustachian tube.

The nasopharynx is very rich in lymphoid or *adenoid tissue* and a mass extending around its posterior wall between the orifices of the Eustachian tubes is known as the **pharyngeal or Luschka's tonsil**, which is often hypertrophied. Reaching from this point forward the mucosa of the roof and upper part of the pharynx is rich in similar tissue which, when hypertrophied, gives rise to **nasopharyngeal adenoids**. The latter obstruct the posterior nares ; compress the openings of the Eustachian tubes ; cause mouth breathing, frequent colds, running of the nose, lack of development of the nose and the body of the maxillæ ; affect the voice ; are a common cause of deafness and otitis media and are often associated with mental apathy and dullness. After puberty they tend to diminish and the nasopharynx also becomes more capacious ; but before this time they should be removed, if well marked, to avoid the evil consequences.

We have already seen the position of the openings of the **Eustachian tubes** (see p. 58) and of **Rosenmüller's fossa** (*recessus infundibuliformis*) just behind it. The latter lies beneath the tip of the petrous bone and if the pharyngeal tonsil is enlarged this fossa may be reduced to a narrow fissure. The **pharyngeal bursa** is the pharyngeal end of the diverticulum that forms the hypophysis cerebri and is present in infancy but has generally disappeared in adult life. It is a median recess opening below the pharyngeal tonsil and reaching upward toward the pharyngeal tubercle.

The **roof and posterior wall** of the nasopharynx is formed by the obliquely sloped under surface of the *basilar process* of the occipital bone and the thick layer of ligaments and fibrous tissue which fills in

the angle between the occipital bone and the vertebrae. From this fibrous tissue, or the periosteum, spring the **nasopharyngeal polypi** which may be pedunculated or sessile, benign or sarcomatous and which occur most often in male children. Even when benign they may by their growth fill up the nasopharynx, depress the soft palate, become *prolonged* into the nasal fossæ, the maxillary sinuses and even through the sphenopalatine foramen and they may possibly erode the base of the skull. Their *removal* if pedunculated may be secured by a wire snare or galvano-cautery loop introduced through the nose, through a temporary resection of the maxilla, a division of the palate and in many other ways. After about twenty years of age they grow much less rapidly or not at all and are even said to atrophy, hence the removal of a small one at this time may be unnecessary as far as its mechanical obstruction is concerned.

The lower part of the pharynx is *funnel-shaped*, narrowing to its narrowest point at its lower end. All below the nasopharynx is lined by stratified epithelium. The fan-shaped *constrictor muscles* overlap one another from below upward. Beneath the inferior constrictor passes the inferior laryngeal nerve, between the inferior and middle constrictors the superior laryngeal nerve and artery pierce the thyrohyoid membrane to reach the larynx and between the middle and superior constrictors the glossopharyngeal nerve and the stylopharyngeus muscle pass downward and inward. The stylo- and palatopharyngei both elevate the pharynx, the former also widens it and the latter narrows very strongly the isthmus of the fauces and helps to shut off the mouth from the pharynx in the second act of deglutition.

The **lymphatics** of the pharynx pass to the upper deep cervical nodes whose enlargement may depend upon an inflammation or some other affection of the pharynx. The lymphatics of the upper part of the pharynx first pass through the postpharyngeal node.

## THE NECK.

The neck or the *passageway* between the head and the thorax is subject to wide *variations* as to its *length*, *size* and *shape*. The abundance or lack of adipose tissue is largely responsible for the increase or decrease of size and for the rounded or angular shape. In extension of the neck its anterior part is lengthened and in flexion is shortened so that the distance of its movable parts from the sternum or the lower jaw varies as does also the relation of these parts to the vertebrae. Hence in giving the relative position of its landmarks the neck is supposed to be in the position midway between flexion and extension, *i.e.*, the natural upright position, unless otherwise stated.

### Landmarks and Surface Markings.

**Anterior Median Region.**—In the receding angle of the chin the **hyoid bone** and its great cornua can be made out. The **body** of the bone

is on a level with the fourth cervical vertebra and nearly on a level with the angles of the jaw. The upper borders of the *cornua* are guides to the lingual arteries which run just above them. Below the hyoid bone is the **thyrohyoid membrane** which corresponds posteriorly with the epiglottis and the upper aperture of the larynx. It is limited inferiorly by the **thyroid cartilage** which is one finger's breadth below the hyoid. The parts of the thyroid cartilage and the **cricothyroid space** between it and the cricoid cartilage below can be readily made out. The projection of the **thyroid angle** is much more prominent in males after puberty, but the **cricoid** is always to be made out. It corresponds to the upper end of the *sixth cervical vertebra*, to the junction of the pharynx and cesophagus and of the larynx and trachea and to the crossing of the common carotid by the omohyoid muscle. Below the cricoid the **trachea** may be felt but its individual rings can not be distinguished. As it descends it becomes less easily felt, for it is covered more deeply by the lower thicker part of the neck so that at the *episternal notch*, on a level with the disc between the second and third thoracic vertebrae, it lies nearly  $1\frac{1}{2}$  inch from the surface.

The **thyroid gland** cannot be distinctly felt unless enlarged. On deep pressure opposite the **cricoid cartilage**, over the line of the carotid artery, the prominent anterior tubercle of the sixth cervical vertebra can be felt and the artery can be compressed against it, as advised by Chassaignac. Hence it is called the **carotid tubercle** or Chassaignac's tubercle. As the omohyoid crosses the carotid at this point the latter is more superficial and more easily compressed above it.

In the median line at the back of the neck there is a slight depression between the prominences which are due to the trapezius and complexus muscles on either side. At the upper end of this depression is the **occipital protuberance**, a little way below this the **spine of the axis** can be felt on deep pressure and below this the spines of the third, fourth, fifth and sixth vertebrae can be felt as a bony ridge but not as individual spines. The spine of the **vertebra prominens** (seventh cervical) can be very plainly felt and represents the lower limit of the neck. In some cases the sixth spine is unusually prominent so that it can be distinctly felt and may be mistaken for the seventh spine.

At the side of the neck the **transverse process** of the *atlas* may be felt just below and in front of the tip of the mastoid process and in the upper part of the supraclavicular fossa the **transverse process** of the *seventh cervical vertebra* can be felt on deep pressure. The angle between the submental region and the neck corresponds about to the hyoid bone and is continued as a groove and a crease in the skin backward and upward beneath the angle of the jaw to the subauricular depression in front of the mastoid, behind the jaw and below the ear. In very fat subjects it may not be present. The groove corresponds to Kocher's incision for the upper cervical triangle.

The **sternomastoid muscle** is altogether the most important landmark of the neck. It is prominent in thin subjects and when thrown into action. Its **anterior border** is the thicker and better marked and

along it runs a communicating branch from the facial to the anterior jugular vein in the lower part of the neck. Extending from the tip of the mastoid to a point just internal to the sternoclavicular joint, this border *overlies the common carotid* and is the *guide for many incisions*. The *sheath* of the muscle which is derived from the superficial layer of the deep cervical fascia is thicker near the middle of the muscle than below or above. The *triangular interval between the sternal and clavicular heads* of the muscle is very evident in thin subjects. Beneath the lower end of this interval, *i. e.*, just above the sternoclavicular joint, lies the common carotid on the left and the bifurcation of the innominate artery on the right side, and on both sides the margin of the pleura and lungs at a deeper level.

The *action* of the sternomastoid of one side is to flex the head forward and to the side of the muscle and rotate it to the opposite side. The fibers from the sternal fasciculus cross superficial to those of the clavicular portion so as to be inserted behind them above. The *clavicular portion* produces the lateral flexion, the *sternal portion* the rotation. This difference of action is important and is illustrated in **torticollis** or **wryneck**, a condition often congenital, sometimes acquired and due to a *contracture* or *spasmodic contraction* of one muscle or the paralysis of the opposite one.

The *congenital cases* are *due* most often to an injury at birth, too great traction on the after-coming head or the pressure of the forceps. A *haematoma* forms within the sheath of the ruptured or injured muscle and the injured part is replaced by fibrous tissue, or the pressure of the extravasation causes an *ischaemic degeneration* and *contracture*. According to some the latter may occur from pressure in *utero*. The deformity may not be noticed for some time after birth and increases with the cicatricial contraction of the injured muscle and cervical fascia and with the diminished growth of the muscle. In this form of wryneck the *treatment* is *division of the muscle*. This was formerly practiced *subcutaneously* 2 cm. above its lower end in adults, 1 cm. above in children, so as to avoid the anterior jugular vein which passes beneath the lower end of the muscle to join the external jugular, which lies along its posterior border. The latter vein is generally out of danger as *only the sternal portion* of the muscle is usually *divided*, for it is the rotation due to this portion which is particularly characteristic of torticollis. The great vessels are not in danger as they are here overlapped by the sternohyoid and sternothyroid muscles. The *open division* is far *preferable* as everything can be divided that prevents the correction of the deformity including the contracted sheath and the cervical fascia. It should be done before secondary changes in the vertebræ and soft parts have taken place. **Spastic wryneck** may be due to a reflex irritation. The *spinal accessory nerve* together with filaments from the anterior divisions of the second and third *cervical nerves* supplies the muscle. In such forms of wryneck the *spinal accessory* is often *excised* and may be *exposed* where it reaches the anterior border of the muscle, 1 to  $1\frac{1}{2}$

inch below the tip of the mastoid. This nerve traverses the muscle about the junction of its upper and middle thirds, emerges at the posterior border a little above its middle, crosses the posterior triangle and passes under the trapezius on a level with the seventh cervical spine. It supplies the latter in conjunction with the third and fourth cervical nerves. In some *severe cases* of spastic wryneck the trapezius and other muscles at the back of the neck are involved and besides the spinal accessory the upper four cervical nerves may require resection.

Besides forming a *guide for the incision in many operations* the sternomastoid divides the antero-lateral region of the neck, in front of the trapezius muscle, into two triangles. These primary surgical triangles are subdivided into several smaller surgical triangles by muscles which are also of service as landmarks in operations on the neck. These triangles bounded by and containing landmarks are of practical use, for their contents can be located with reference to these boundaries and landmarks.

**The posterior triangle** (Fig. 29) is subdivided by the posterior belly of the omohyoid into an inferior or subclavian and a superior or occipital triangle. The occipital triangle bounded by the sternomastoid in front, the trapezius behind and the omohyoid below contains comparatively little of practical importance. The superficial cervical nerves appear at the posterior border of the sternomastoid. The small occipital, great auricular and transverse cervical nerves emerge just above the center of the muscle, the first running up to the scalp near the posterior border of the muscle, the second across the muscle to the back of the ear, the third straight forwards across the muscle. Lines drawn from the middle of the posterior border of the muscle to the sternum, the middle of the clavicle and the acromion represent the course of the suprasternal, supraclavicular and supraacromial nerves. The spinal accessory crosses this triangle as described above.

**The subclavian triangle** (Fig. 29) corresponds about to the wide depression above the clavicle, the supraclavicular fossa, which is well marked except in stout subjects and infants. In some *fractures of the clavicle* this fossa may be obliterated or even replaced by a prominence. This triangle is bounded below by the clavicle, above by the posterior belly of the omohyoid and in front by the posterior border of the sternomastoid. The posterior belly of the omohyoid can be made out in thin necks and especially when in action. It runs along a little above the clavicle, inclining somewhat upwards as it passes forwards to pass beneath the sternomastoid. The posterior border of the latter can be made out when in action. The attachment of its clavicular portion varies in width and in some cases, especially in muscular subjects, it encroaches on the subclavian triangle so as to require division in operations in this region.

At a deeper level the posterior border of the scalenus anterior muscle roughly corresponds to that of the sternomastoid though it has a somewhat different direction. Hence we may say that there are two

## PLATE VIII.

FIG. 29.

The occipital and subclavian triangles. The head is turned away to the left and the clavicle is strongly depressed. (The posterior scapular artery is unusually deep and has separated unusually early from the superficial cervical artery.) (Zuckerkandl.)

triangles of which the deeper is bounded in front by the scalenus anterior. The **phrenic nerve** lies in front of this muscle and crosses it obliquely, being directed toward the lower end of its inner border, where it passes behind the subclavian vein. This nerve *commences* about the level of the hyoid bone and is *formed by* branches from the third and fourth cervical. It lies deeply and descends underneath the sternomastoid, being about midway between its two borders at the level of the cricoid cartilage.

Crossing the subclavian triangle in a line from the angle of the jaw to the center of the clavicle is the **external jugular vein**. It crosses the sternomastoid obliquely to reach its posterior border, the lower third of which it follows. The lower dilated end or "*sinus*" of the vein, between a point  $1\frac{1}{2}$  inches above the clavicle, where it pierces and is adherent to the deep cervical fascia, and its entrance into the subclavian vein in front of the scalenus anterior, receives the transverse cervical and suprascapular veins. These veins sometimes present a plexiform arrangement in the subclavian triangle and may render more difficult the operations in this triangle. Owing to its adherence to the deep cervical fascia the "*sinus*" of this vein *remains patent* and is liable to *admit air* when it is opened.

At the base of the triangle the **subclavian artery** describes a *curve* from the sternoclavicular joint to the center of the clavicle, the highest point of the curve rising  $\frac{1}{2}$  to 1 inch above that bone. On the *left side* the artery lies more deeply and does not rise so high in the neck as on the right side. At the outer border of the sternomastoid and just above the clavicle the *pulsation* of the artery may be felt and it may be *compressed* against the first rib by pressure downward and backward, when the arm is drawn downward. Normally the artery does not rest directly upon the rib but is slung, as it were, one fourth inch or more above it between the scaleni anterior and medius.

The **artery** may be *ligated* in its third portion; which lies in this triangle external to the scalenus anterior, by an *incision* about four inches long a finger's breadth above the clavicle. The *layers divided* in reaching the artery are the following: (1) Skin; (2) scanty subcutaneous connective tissue; (3) platysma; (4) second connective tissue layer with fat; (5) superficial layer of deep cervical fascia, from the sheaths of the sternomastoid and trapezius; (6) third layer of loose connective tissue; (7) middle layer of deep cervical fascia, forming the sheath of omohyoid and connected with the subclavian vein; (8) fourth layer of connective tissue in which lie the lymph nodes, the end of the external jugular vein, the subclavian artery and vein and their branches, and the brachial plexus, etc. The *external jugular vein* (see above) should be *cut* between two ligatures as should also the suprascapular vein. The *suprascapular* and *transverse cervical branches* of the subclavian artery run outward parallel with the clavicle, the former behind, the latter just above it where its pulsation may usually be felt. The *supraclavicular nerves* descend in front of this triangle. The **subclavian vein** lies at a lower level, below, internal to and in front

of the artery and under cover of the clavicle. To avoid injury to the vein the *aneurism needle* should be passed from below and in front.

At the inner end of this triangle the *subclavian vein* is separated from the artery by the *scalenus anterior*. Behind the latter the *artery* lies in contact with and grooves the *dome of the pleura* and the apex of the lung. These structures should be carefully avoided in passing the ligature. Strict asepsis should be observed to avoid inflammation of the pleura and empyema. The *pleura* has also been *opened* in removing deeply seated tumors of the base of the neck and, together with the lung, has been wounded in stab wounds of the neck and by bony fragments in severe fractures of the clavicle or first rib. *Abscess* in this part of the neck has opened into the *pleura* and *pleurisy* has also followed cellulitis of this part. Hernia of the lung into the neck during violent paroxysms of coughing has been reported. For the position of the lung and *pleura* in the root of the neck see p. 215.

**The brachial plexus** can be *felt* and, in very thin subjects, even seen in the subclavian triangle. Its *upper limit* is shown by a line from the side of the ericoid cartilage to a point a little external to the middle of the clavicle. It *lies* just above the subclavian artery, its lowest cord being partly behind the artery, and it emerges like the artery from between the anterior and middle scalene muscles. Hence it is exposed and may serve as a *guide in ligating* the subclavian artery. It has occasionally happened that a cord of this plexus has been included in the ligature in place of the artery but the mistake is evident from the continued pulsation in the arteries of the arm.

The **third portion of the artery** is the *seat of election* for ligature for it is more superficial and has no branches and fewer vital relations. The **second part** lies deeply behind the *scalenus anterior* on which lies the *phrenic nerve*. It includes the highest point of its curve, gives off *one branch* (*superior intercostal*) and is in close *relation* with the *pleura*. The **first portion** is *crossed* in front by the *internal jugular*, *vertebral* and the commencement of the *innominate veins*, and on the right side by the *pneumogastric* and a loop of the *sympathetic nerve*. On the left side the *thoracic duct* arches over it. The *subclavian vein* is below and in front of it and gives off three large *branches*. *Below and behind* it are the *pleura* and *lung* and, on the right side, the *recurrent laryngeal nerve*. Hence and because of its deep situation it is not well suited for the application of a ligature.

After ligature of the second and third portions of the subclavian the **collateral circulation** is established and carried on principally through the *anastomoses*, (1) of the *suprascapular* and *posterior scapular* with the *acromiothoracic*, *infra-* and *subscapular* and *dorsalis scapulae*; (2) of the *superior intercostal*, *aortic intercostal* and *internal mammary* with the *long thoracic* and the *scapular arteries*; (3) of small branches in the *axilla*.

**Cervical ribs** occur usually on both sides, sometimes on one side only. As a rule they are articulated with the *seventh cervical vertebrae* and its *transverse process* but sometimes they are fused with it. They may

be very short, when they are often mistaken for *exostoses*, or they may extend well forward and be connected by bony, cartilaginous or fibrous union with the first rib, its cartilage or the sternum. In such cases the *subclavian artery* and *brachial plexus* pass over them and the anterior, and sometimes the middle, scalene muscle is attached to them. The distinct *pulsation* of the artery at a high level in such cases may lead to a diagnosis of *aneurism* and in fact the latter condition seems to be not uncommonly associated with cervical ribs. The rib may form a distinct projection in thin persons but as a rule it causes no *symptoms*. Sometimes however the circulation in the arm and the function of the branches of the brachial plexus is interfered with, apparently as the result of *pressure* by the ribs or of the *sharp bend* in the artery, and hence *removal* of the rib is indicated.

The **anterior cervical triangle**, in front of the sternomastoid, is subdivided by the digastric muscle above and the anterior belly of the omohyoid below into three smaller triangles.

The **submaxillary triangle**, or the upper one of these three, is bounded above by the lower border of the jaw and the line of this continued back to the mastoid process, below by the posterior belly of the digastric muscle and the hyoid bone, in front by the median line. It corresponds to the *suprathyroid region* of some authors. That part of its posterior angle behind the thick fascial band from the sheath of the sternomastoid to the angle of the jaw, belongs to and has been described under the parotid region. The *posterior belly of the digastric muscle* coincides with a line from the mastoid process to a point just above the junction of the great cornu and body of the hyoid bone.

In the normal position of the head this region lies in a nearly horizontal plane which accounts for the rarity of wounds here. When the head is extended, as it is in operations on this region, the latter is oblique from above downward and inward. In incisions into it we meet the following layers in succession, (1) skin ; (2) platysma, with a connective tissue layer on either side ; (3) the superficial layer of the deep cervical fascia forming a sheath for (4) the submaxillary gland ; (5) the muscular floor of the triangle with vessels and nerves covered by a deeper layer of fascia which is attached to the hyoid bone and the mylohyoid ridge and forms a sheath for the digastric muscle.

The **platysma** is quite closely connected with the skin so that the edges of wounds crossing the course of the muscle are likely to be turned in. Owing to the loose tissue beneath the muscle the skin and platysma may be readily used as a *flap* and the flap so formed can be freely displaced to cover defects in the lower lip and lower part of the face. But to cover defects in the lips or cheek such flaps possess the disadvantage of not being lined by mucosa so that the final results are disappointing, owing to the adhesions and contraction of the flap (see p. 99). The amount of fat between the skin and deep fascia is very variable. There is often a diffuse deposit of fat, especially in the area between the chin and the hyoid bone, producing the so-called *double or triple chin*, thus converting the normal concavity of this region into a convexity.

The superficial layer of the deep fascia splits to enclose the *submaxillary gland* in a fibrous sheath and is *adherent* to the lower border of the jaw and to the hyoid bone. It is *continuous* laterally with the sheath of the sternomastoid and of the parotid gland and in the median line with the similar layer of the opposite side. It is connected with the thick *fascial band* from the sternomastoid to the angle of the jaw, which separates the submaxillary from the parotid sheath.

The **submaxillary gland** differs from the parotid in that its fibrous septa are not closely connected with the inside of its sheath, but it is separated from its sheath by loose connective tissue so that it can be readily enucleated. The submaxillary gland is *seldom inflamed* primarily, though of all salivary glands it is most frequently the seat of *calculi*, which by obstructing the duct may produce sudden, recurring attacks of acute, painful *swelling* of the gland, sometimes accompanied by suppuration.

The *contents* of the submaxillary gland *sheath* of the most practical importance are the **lymph nodes** on the surface of the gland which receive lymphatics from the lips, the fore part of the tongue, the floor of the mouth, the nose, the forehead, the nasal half of both eyelids and the submaxillary and sublingual glands. Hence these nodes may be *affected* in any inflammatory affection or malignant new-growth of these parts, and the enlarged or broken-down nodes require *opening* or *removal* according to circumstances. When these lymph nodes are removed it is often impossible to spare the gland, especially in cancerous conditions, and the entire contents of the digastric triangle are then removed together. In this procedure the most *important relation* of the gland is with the **facial artery** which grooves its postero-superior part passing from its deep surface to the border of the jaw just in front of the masseter.<sup>✓</sup> The general *direction* of the tortuous facial artery is between the latter point and its origin just above and outside the tip of the great cornu of the hyoid bone, passing beneath the posterior belly of the digastric in its course. The **facial vein**, usually separated from the artery by the submaxillary gland, the posterior belly of the digastric, the stylohyoid muscle and the hypoglossal nerve, crosses superficial to the artery to become more *posterior* at the border of the jaw. The *submental branch*, given off from the artery beneath the gland, runs forward on its deep surface. (Fig. 30.)

When *enlarged* the posterior extremity of the gland, grooved by the facial artery on its deep and superior aspect, may *overlap* the *external carotid* from which it is *separated* by the posterior belly of the digastric, the stylohyoid and the band from the sternomastoid to the angle of the jaw. The gland lies partly hidden beneath the mandible. Its **accessory portion and duct** (*Wharton's*) (see page 106), pass forward in the floor of the mouth on the deep surface of the mylohyoid. Notice the close relation between this region and the floor of the mouth; inflammatory affections may spread from one to the other behind the mylohyoid. In this connection it should be remembered that the commonest cause of *abscess* in the submaxillary region is *dental caries*.

PLATE IX.

# PLATE X.

FIG. 31.

Submaxillary triangle and the deep relations of the submaxillary gland. Dotted white line indicates the position of the gland, dotted red line the course of the lingual artery beneath the hyoglossus. (Testut.)

FIG. 32.

Structures of the upper part of neck in the superior carotid and submaxillary triangles. The sternomastoid muscle is retracted somewhat backward, the digastric is divided and the omohyoïd removed. (Zuckerkandl.)

followed by alveolar periostitis of the mandible (see pages 100-1). Inflammation of the submaxillary gland and of the lymph nodes within its sheath, or the abscess resulting therefrom, is more circumscribed than the last-mentioned abscesses and in opening submaxillary abscesses it should be remembered that the facial vessels and their branches are beneath the sheath and not exposed to injury.

The two bellies of the digastric below and the jaw above frame a deep triangle lodging the submaxillary gland. The floor of this triangle is formed by the mylohyoid and hyoglossus muscles from before backward. Passing forward on the latter muscle is the *hypoglossal nerve* accompanied by the *ranine vein*. The *lingual artery* has much the same course, at a somewhat lower level, but it lies beneath the hyoglossus and upon the genioglossus muscle. This artery, arising opposite the tip of the great cornu of the hyoid, runs forward just above that process and is usually ligated in the "lingual triangle." This triangle is bounded above by the hypoglossal nerve, in front by the posterior border of the mylohyoid and behind and below by the posterior belly of the digastric. (Fig. 31.) It is readily exposed on turning up the submaxillary gland. The lingual artery is here reached by separating the more or less vertical fibers of the rather thin hyoglossus muscle, at right angles to which it runs. It is accompanied by one or several *venae comitantes*.

To include the *dorsalis linguae* branch it has been advised by Farabœuf and others to ligate the first portion of the artery, behind the hyoglossus muscle near whose posterior border this branch is given off and passes upward. For this purpose the end of the great cornu of the hyoid bone is our guide, to which the posterior fibers of this muscle are attached. This part of the artery is crossed by the hypoglossal nerve, the facial and lingual veins and the digastric and stylohyoid muscles.

The *sublingual artery*, usually given off at the anterior border of the hyoglossus, may sometimes arise in the lingual triangle and might then be ligated in place of the trunk, so that the circulation on the same side of the tongue would not be controlled by the ligature. This is probably not the common cause of hemorrhage in operations on the tongue after ligation of the lingual but rather an *anomaly* wherein the lingual on one side is small and its place is taken by a large branch from the opposite lingual.

Underneath the deep fascia in the median line beneath the chin and lying on the mylohyoid muscle are two or three *lymph nodes* which receive vessels from the middle of the lower lip and the chin and may be enlarged in affections of these parts.

The submaxillary gland and its surrounding lymph nodes are comparatively superficial and may be easily reached for removal or for elevation to expose the lingual triangle, by a curved incision from just below the angle of the jaw to the body of the hyoid bone and up toward the symphysis. Kocher's so-called "normal incision" for the upper lateral cervical triangle passes from in front of the tip of the

mastoid to the middle of the hyoid bone and lies just below the digastric and the other suprathyroid muscles. It avoids important nerves, for those crossing it can be retracted posteriorly, and it crosses the point where the branching of the great vessels occurs.

The **subhyoid region** is divided into the *two carotid triangles* by the anterior belly of the omohyoid muscle. The latter follows a line from the side of the body of the hyoid at its lower border to the anterior border of the sternomastoid at the level of the cricoid cartilage, where it crosses in front of the common carotid and behind the sternomastoid.

The **superior carotid triangle** is bounded behind by the sternomastoid, above by the posterior belly of the digastric and below and in front by the anterior belly of the omohyoid. Its *floor* is formed by the thyrohyoid, hyoglossus and inferior and middle constrictors of the pharynx. It contains, beneath the skin the platysma and the superficial and middle layers of the deep cervical fascia, the lower portion of the external carotid with the commencement of its lower five branches and, beneath the anterior margin of the sternomastoid, the upper end of the common carotid and the lower part of the internal carotid.

The **superior thyroid artery** arises a little below the great cornu of the hyoid and runs downward and forward to the back part of the thyroid cartilage and the upper and outer part of the thyroid body. It is superficial only at its commencement. Beneath it is the *superior laryngeal nerve* whose internal branch, with the superior laryngeal branch of this artery, pierces the thyrohyoid membrane. Its *sternomastoid branch*, arising about half an inch from its origin, crosses the upper end of the common carotid to reach the sternomastoid muscle.

The **occipital artery**, arising at the same level as the facial (p. 124), but from the posterior aspect of the artery, passes upward and backward to the interval between the mastoid process and the transverse process of the atlas. It finally enters the scalp with the great occipital nerve midway between the mastoid process and the external occipital protuberance and follows thence the line of the lambdoid suture. The facial and lingual branches have already been referred to.

The **inferior carotid triangle** is bounded above by the anterior belly of the omohyoid, behind by the sternomastoid and in front or mesially by the median line. The carotid triangles are so called from their containing the carotid vessels which strictly speaking are in great part behind these triangles under cover of the anterior border of the sternomastoid.

**The Great Vessels.**—The line of the carotid is from the sternoclavicular joint to a point midway between the angle of the jaw and the mastoid process. The **common carotid** extends up to the upper border of the thyroid cartilage, on a level with the third cervical vertebra, where it bifurcates into the external and internal carotids. At its point of *bifurcation* it presents a slight *dilatation* which is the most common situation for *aneurisms*, for there appears to be some resistance to the blood current here. Such an aneurism may demand the *proximal*

*ligature* of the carotid. The carotid, having no collateral branches, is also the vessel in which the *distal ligature* (Basador's method) is best adapted. It is most often practiced for aneurisms in its lower part, where they are not uncommon. As there are no collateral branches between the aneurism and the ligature the latter, by occluding the artery, prevents the blood passing through the aneurism. *Wardrop's operation*, or the distal ligature of large branches for aneurism of a main trunk, has been tried here and is now limited to the ligature of the carotid and the third portion of the subclavian for aneurisms of the innominate or, occasionally, of the aorta. But as there are large branches given off from the first and second portions of the subclavian, which under the conditions present can scarcely be ligated, the success of this method is not so great as it might otherwise be.

The **common carotid** is now *ligated* mainly for aneurism or wound of the artery itself. The *external or internal carotid*, instead of the common carotid, is now *ligated* to check hemorrhage from their branches due to wounds, to prevent hemorrhage in the removal of neoplasms and to check the growth of the latter. One objection to ligature of the common carotid is the occasional *effect on the brain*, but as a rule the two vertebrals and the opposite carotid with their free anastomosis in the circle of Willis are sufficient to obviate this. The *common carotid* may be secured at any part in the neck but the **place of election** is just above the omohyoid, where it is superficial, being covered only by the skin, platysma and superficial and middle layers of the deep cervical fascia.

The **incision** is carried along the *anterior border* of the *sternomastoid* with the center opposite the cricoid cartilage. A communicating vein between the facial and the anterior jugular veins may be met with in the line of incision. After incising the superficial layer of the cervical fascia along the anterior border of the sternomastoid we meet the *omohyoid* crossing obliquely the line of incision at the level of the cricoid cartilage. Then, incising the middle layer of the cervical fascia above the omohyoid in the same line, we expose the *carotid sheath* which is here crossed by the *sternomastoid artery* and sometimes by the superior thyroid veins. The middle thyroid veins may also cross it here but usually with the omohyoid muscle. A valuable guide to the artery, about the crossing point of the omohyoid and about  $2\frac{1}{4}$  inches above the clavicle, is the *carotid tubercle* or anterior tubercle of the sixth cervical vertebra, directly over which lies the artery and against which it may be compressed.

This tubercle serves also as a *guide* to the **vertebral artery** which lies on the transverse process of the seventh cervical vertebra just below it, crossed by the inferior thyroid artery and, on the left side, by the thoracic duct. It is less often tied than formerly. *Below the omohyoid* the carotid artery lies more and more deeply, as we follow it to the base of the neck, being overlapped in front by the sternohyoid and sternothyroid muscles and to some extent by the thyroid body, especially if the latter is enlarged. *Near its lower end* the anterior

jugular vein crosses in front of it and the inferior thyroid artery and recurrent laryngeal nerve behind it.

The **carotid sheath**, derived from the deep layer of the deep cervical fascia, encloses the internal *jugular vein* and the *vagus nerve* in addition to the artery. The sheath should be *opened* from the inner side to avoid the thin-walled vein which is external and, being nearly twice the size of the artery, overlaps the latter anteriorly. On the right side *the vein*, which is commonly larger than that on the left, becomes a little separated from the artery at the root of the neck while on the left side the vein overlaps the artery still more at this point. Although each of the three occupants of the sheath has its own special investment there is danger of wounding the vein in passing the *aneurism needle* and to avoid this danger the latter is *passed from without* inward after carefully separating the vein and artery.

In exposing the sheath of the carotid the *descendens noni nerve* is found in front of it, inclining gradually from the outer to the inner side. Care should be taken to *avoid it* as it supplies the infrahyoid muscles. It is sometimes found within the sheath.

As before stated the **external carotid** is now *ligated* for many conditions for which the common carotid was formerly tied. Thus it is ligated for wound or aneurism of its branches, as a preliminary measure in certain operations (like excision of the parotid, maxilla, etc.) and as a palliative measure in malignant neoplasms to starve them or prevent hemorrhage. For the latter purpose *excision* is more effective than ligature. Ligature, and especially excision, of the external carotid is less easy but safer and more satisfactory than ligature of the common carotid.

The **line of the external carotid** inclines forward from the line of the sternomastoid to reach a point beneath the angle of the jaw. In the *natural position*, when the angle of the jaw about touches the sternomastoid, the *line of the artery* nearly corresponds to the anterior border of the muscle, but in the *extended position* of the head, in which the operation is done, the line of the artery is from the angle of the jaw to the sternomastoid at the upper border of the thyroid cartilage.

The **incision** for ligature or excision may be made in this line or across it, in the line of Kocher's normal incision (p. 125). In its *lower part* the artery is comparatively *superficial*, being covered by the same layers which cover the upper part of the common carotid (p. 127), but it soon becomes more deeply placed and passes beneath the digastric and stylohyoid muscles and then internal to and within the parotid gland. Below the digastric, which crosses it about  $1\frac{1}{4}$  inch above its commencement, it is crossed by the hypoglossal nerve and below this by the facial and lingual veins, usually as a common trunk which is often joined by the superior thyroid vein. The **place of election** for ligature is between the superior thyroid and the lingual branches, or opposite the tip of the great cornu of the hyoid bone. Through the *same incision* the *four lower branches* of the external carotid can be *ligated* at their origin.

In the first part of its course the external carotid is situated internal (mesial) and anterior to the internal carotid, in the loose connective tissue in which both are lodged, hence the question may arise whether the vessel exposed is the internal or external carotid. The *following points* help us to distinguish the *external carotid*, (1) the presence of branches; (2) the stoppage of pulsation in its branches from compression of the artery; (3) contact with the hypoglossal nerve which crosses it just below the origin of the occipital branch, and (4) its near relation to the great cornu of the hyoid.

In passing the *aneurism needle* care is needed to avoid the superior laryngeal nerve which passes beneath it in this situation. The artery may also be tied beneath or above the digastric but it lies deeper here and is more difficult to expose. Some distance above the muscle the glossopharyngeal nerve passes obliquely beneath the artery. For the various *anomalies* and variations of the external carotid descriptive text-books may be consulted but one may be mentioned which I have found in a preliminary ligature of this vessel, *i. e.*, the absence of an external carotid trunk and the giving off of the branches in an axis manner.

The *internal carotid* may be *exposed* and *ligated* in much the same manner and with the same precautions as the common carotid, of which it appears to be the continuation as to its course and relations. What has been said above as to the relations of the common carotid and its branches is equally and more frequently useful in the numerous operations for various conditions in which these vessels are exposed and avoided, as in *tubercular lymphadenoma* of the neck, etc.

The *internal jugular* and the other veins of the neck, as well as the subclavian and axillary veins, are subject to the *respiratory wave* (or venous pulse). This is indicated by their being more or less emptied in inspiration and distended in expiration and is due to the alternately decreased and increased intrathoracic pressure acting on the right heart and the venous trunks. When one of these veins is wounded air is liable to be drawn in during the *inspiratory aspiration* of its contents provided the wound is dry or the vein is not immediately compressed between the wound and the heart. Nothing prevents the passage of this air to the right auricle of the heart. Hence pressure should be at once made at the wound of the vein or on its cardiac side. Aspiration of air into veins is not so frequent an accident as is generally supposed, and as might be expected from the above. It is not likely to happen if the peripheral flow of blood to the wounded spot is unobstructed, or if the wall of the vein is healthy and its wound is not held open, for then atmospheric pressure causes it to collapse. It is favored by the elevation of the wounded part and it may occur beyond the limits of the venous pulse. When large amounts of air are aspirated it may cause death rapidly by over-distension and paralysis of the right heart, or more slowly by asphyxia from air embolism of the pulmonary vessels. The entrance of smaller quantities of air is usually recovered from.

The *cervical portion of the sympathetic gangliated cord* lies close be-

hind the carotid sheath and in front of the prevertebral fascia. It lies slightly internal to the vagus nerve which is within the sheath. It consists of three composite ganglia united by intervening nerve cords.

The superior cervical sympathetic ganglion (2.5 to 3.75 cm. long) lies in front of the second and third cervical transverse processes. It is connected above with the carotid and cavernous plexuses, below with the smaller middle or thyroid ganglion, situated where the cord crosses in front of and behind the inferior thyroid artery at the level of the sixth cervical vertebra. The middle is connected with the inferior ganglion by cords which pass both behind and in front of the subclavian artery. The inferior ganglion, larger than the middle, is deeply placed between the seventh cervical transverse process and the neck of the first rib, behind the vertebral artery.

As far as we now know the functions of the *cervical sympathetic* it contains dilator fibers of the pupil, motor fibers of the involuntary muscles of the orbit and eyelid, vaso-motor fibers of the head, accelerator fibers of the heart, besides secretory fibers of the salivary glands. From theoretical considerations the *excision* of the superior or all the cervical ganglia has been proposed for glaucoma, exophthalmic goitre, and epilepsy.

The *superior ganglion* alone requires *removal for glaucoma* and it is followed by contraction of the pupil, retraction of the globe, some ptosis and the diminution of the ocular pressure (see p. 71). The contraction of the pupil is temporary, lasting only a few days and so is usually the ptosis. As the superior ganglion inhibits the vaso-constrictors of the carotid region only, the inferior ganglion, which does the same for the vertebral region, must also be removed to *alter the cerebral circulation in epilepsy* and improve the nutrition of the brain, by substituting hyperæmia for anaemia. The results in epilepsy have not been very satisfactory. For *exophthalmic goitre* the resection of the superior ganglion for exophthalmos and the middle and inferior for the goitre and tachycardia have given some encouraging results. Hence for epilepsy and Graves' disease the resection of the entire cervical sympathetic is advisable but from the anatomical relations above given it is evident that the operation on the middle and inferior ganglia is one of great delicacy. The *cervical sympathetic* may be exposed by an *incision* along the anterior or posterior border of the sternomastoid more readily than might be supposed. *Unilateral division of the vagus nerve* may be made without danger to life or even without disturbance to the patient.

**The Hyoid Bone.**—*Fracture* of this is rare but it may occur in hanging or from blows, falls, throttling or even muscular action. Its usual situation is at or near the junction of the great cornu with the body of the bone. It causes pain on speaking, swallowing, opening the mouth, moving the tongue, or on pressure. It is not often serious of itself but its associated injuries may be fatal.

Extending between the upper border of the thyroid cartilage and the upper and posterior margin of the hyoid bone is the *thyrohyoid*

**membrane**, about 3–4 cm. in height. Owing to its attachment to the superior border of the hyoid the larynx may be drawn up behind the latter bone. In front of the membrane, and between it and the back of the hyoid bone and the integument and fascia below it, is the **thyrohyoid bursa** which when cystic forms a *median tumor* just beneath the hyoid. If this should be opened, as in case of suppuration, a *fistula* is likely to result unless the lining membrane has been excised, for the constant movements of the parts in swallowing prevent the walls of the cyst from adhering together. *Mesially* the membrane is subcutaneous except for the intervening cervical fascia, *laterally* it is covered by the thyrohyoid and sternohyoid muscles.

Behind the thyrohyoid membrane and separating it from the epiglottis is a mass of *fatty connective tissue* limited superiorly by the mucous membrane at the base of the tongue. Through this tissue and the thyrohyoid membrane the *transverse incision* is carried in **subhyoid pharyngotomy**, keeping close beneath the hyoid bone to avoid the *superior laryngeal nerve* (internal branch) which pierces the membrane on each side. As this is the *sensory nerve* of the larynx wounding it increases the risk of foreign substances passing through the larynx, which involves the danger of aspiration pneumonia. By this operation we may expose and operate upon the larynx above the vocal cords, especially posteriorly, and the lower part of the pharynx.

It is through this thyrohyoid membrane and its over- and underlying parts that **cut throat wounds** are most likely to occur. In such cases the anterior jugular vein, superior thyroid artery and nerve and, if near the hyoid bone, perhaps the lingual artery would be *divided*, besides several muscles, etc. In a *deep wound* the pharynx would be opened and the epiglottis cut near its base. The latter are *serious complications* for the free end of the epiglottis may obstruct the glottis and the blood flowing into the larynx and trachea may also cause asphyxia. Suicidal throat wounds made by right-handed persons are *generally oblique*, passing from the left downward and to the right, and the first part of the wound is often shallow. If the wound be *above the hyoid bone*, the anterior jugular vein, lingual artery, branches of the facial artery, the hypoglossal and lingual nerves and the submaxillary gland, besides several muscles, would be cut. Among the divided muscles are those attaching the tongue to the jaw so that the tongue is liable to fall back upon the larynx and cause suffocation. The tongue itself may be cut and the floor of the mouth freely opened.

Next in frequency to wounds in the thyrohyoid space are those involving the trachea or larynx in which the anterior jugular vein, thyroid gland, superior and inferior thyroid arteries and veins, middle thyroid veins, recurrent laryngeal nerves, trachea and oesophagus, besides the infrathyroid muscles, are cut. There is *danger of blood getting into the trachea and bronchi* in sufficient quantity to produce suffocation. When the trachea is severed or widely opened the voice is lost.

In all such wounds of the neck, suicidal or otherwise, the *great*

vessels often escape in a wonderful manner, being protected in part by their depth and mobility, and in part by the projecting thyroid cartilages and by the contraction of the sternomastoid muscle. Of course in some cases the great vessels are wounded, usually with a rapidly fatal result. In some cases of *gunshot* and *punctured wounds* the vessels seem to have been pushed aside and to have owed their safety to their mobility. The great vessels are more easily wounded in wounds across the cricothyroid space or the upper part of the trachea than in wounds made elsewhere in the neck with equal force. Wounds at the side of the neck have involved a large part of the *brachial plexus* without other important structures. The chief dangers of wounds of the neck are **hemorrhage** and **suffocation**, the latter from blood in the trachea and bronchi or from obstruction of the glottis by the falling back of the tongue or the wounded epiglottis.

The larynx in its **median position** below the thyrohyoid membrane can usually be readily *felt*, especially in males in whom it is larger, so that it stands out between the two sternomastoids. The most prominent part is the anterior mesial border of the thyroid cartilage, 2-3

FIG. 33.

Larynx viewed from above, the vocal cords and arytenoid cartilages widely separated.  
(ZUCKERKANDL.)

cm. in height, whose upper angle is known as the *pomum Adami* or *Adam's apple*. A bursa has been described in front of this prominence by Béchard. In women and children, in whom the neck is more rounded and the larynx is smaller, the latter is less prominent but is usually distinctly felt, and is an important landmark.

The relative **position** of the larynx varies with the position of the neck and the age of the patient. Thus the *lower border of the cricoid cartilage* varies from a point opposite the fifth to one opposite the seventh cervical vertebra, being higher in the young and when the neck is extended. In the *median line* the larynx is *covered* only by the skin and cervical fascia (the anterior and middle layers blended into one), *laterally* by the infrahyoid muscles and the thyroid gland. The *superior aperture* of the larynx, or the space between the aryteno-epiglottic folds, corresponds to the *superior border* of the thyroid car-

tilage, the *glottis*, to the junction of the superior and middle thirds of its anterior border, the laryngeal pouches to about its superior third.

With the *laryngoscope* may be seen the *triangular superior aperture* of the larynx placed very obliquely from above and in front downward and backward. Its *base* is at the epiglottis in front, its *sides* are formed by the aryteno-epiglottic folds in which are two eminences corresponding to the cornicula and cuneiform cartilages, and its *apex* is at the arytenoid commissure of mucous membrane. Between each aryteno-epiglottic fold and the ala of the thyroid cartilage is the shallow depression of the *pyriform sinus*. More deeply are seen the superior or *false* and the inferior or *true vocal cords* with the *ventricle* between the two pairs of cords. Below the glottis a little of the cricoid cartilage and more or less of the anterior tracheal wall is visible and, if the glottis is widely dilated, even the *bifurcation of the trachea* may be dimly seen. The mirror being tilted the image of the epiglottis is in its upper and anterior part, that of the arytenoids in the lower and posterior part, but that of either vocal cord is on the side to which it actually belongs.

The *glottis* (Figs. 21, 33) is the *narrowest part* of the interior of the larynx *measuring* about one inch antero-posteriorly in the adult male, and about three fourths of that in the female and in the male before puberty. Approximately the *anterior two thirds* of the glottis consists of the *true vocal cords*, the posterior third of the interval between the arytenoid cartilages, covered by mucosa. The transverse diameter may equal half its length in extreme dilatation.

On account of its narrow caliber *foreign bodies* of the most varied character may be arrested here, either above or in the *rima* of the glottis according to their size. I recently removed from a one-year-old baby through a high tracheotomy two pieces of egg shell which were caught in the glottis and hung down below it. The *mucosa* of the larynx, supplied by the superior laryngeal nerve, is so *sensitive* that it acts as a *sentinel* at whose warning the glottis closes to keep out foreign bodies, but it is sometimes taken unawares and lets a foreign body through into the trachea. The *danger* of such foreign bodies in the larynx or trachea is not so much due to the mechanical obstruction as to the *reflex spasm* of the glottis which they excite.

A peculiar *spasm of the glottis* of central nervous origin, perhaps due to indigestible food or other reflex cause, occurs in infancy under the name of *laryngismus stridulus* or laryngeal asthma. A similar condition of *spasm of the glottis* in adults may be due to the *pressure* of an aneurism or a tumor on the *recurrent laryngeal nerve*. Such pressure in time paralyzes the nerve so that the vocal cord on the affected side cannot be approximated and consequently the voice is hoarse or lost, a characteristic symptom of many aneurisms of the aortic arch. The opposite cord may however be made to reach beyond the median line in the effort at compensation.

The *caliber* of the *rima glottidis* may be diminished as the result of *strictures* from syphilitic, tubercular or diphtheritic ulceration which

require the long-continued use of an intubation tube or sometimes a more radical operation.

The **shape** of the glottis varies from an extremely narrow vibrating *slit*, in the production of a high note, to an elongated narrow *triangle* with the apex forward, in quiet breathing, or a *lozenge-shaped figure* with a truncated posterior angle in deep respiration. These changes are due to the approximation or separation of the sides of the glottis by means of the approximation or separation of the arytenoid cartilages, and, in the production of the wider lozenge-shape opening, by the rotation of their anterior angles, to which the vocal cords are attached. The glottis is also *closed*, after inspiration, to fix the *diaphragm* in efforts of expulsion, as in defæcation, urination, vomiting and parturition.

The **mucosa** of the true vocal cords is covered by a thin stratified epithelium. There is no loose submucous connective tissue, hence there is little or no chance of acute œdema of the glottis. The so-called "*œdema of the glottis*" occurs in the *aryteno-epiglottic folds* where there is an abundance of submucous tissue. This may rapidly swell in case of laryngitis or irritation by heat, caustics, injury or neighboring inflammatory conditions, and cause obstruction of the superior aperture of the larynx, with dyspnœa. The *mucosa* is *thickest* and the submucosa most abundant in the aryteno-epiglottic folds, the ventricles, the false vocal cords and the under surface of the epiglottis, in the order given, and the degree of congestion and swelling in acute laryngitis varies correspondingly. The result of the swelling is a croupy cough and hoarseness, with dyspnœa in severe cases from obstruction or spasm.

**Laryngeal polypi** of various kinds, either pedunculated or sessile, may grow on the vocal cords or other parts of the larynx and cause aphonia, cough and more or less difficulty in breathing. They may be removed through the mouth, with the aid of the laryngoscope, through an anterior pharyngotomy or by *thyrotomy*. The latter consists of a median splitting of the thyroid cartilage which must be done exactly in the median line so that the opening into the larynx shall be between the vocal cords, otherwise there is great danger of permanently impairing vocalization. This operation may also be applied to the removal of impacted foreign bodies.

The *thyroid*, *cricoid* and *arytenoid cartilages* are composed of *hyaline cartilage* and, like other structures composed of this variety of cartilage, are liable to *ossification*, especially in males after middle life. It occurs first in the thyroid and cricoid cartilages, commences near their articulation and renders the larynx more liable to *fracture*. The latter occurs from lateral or anterior compression by blows, falls, throttling, etc. Fracture is therefore more common in males and in the thyroid cartilage on account of its size, shape and prominence. The *thyroid cartilage* is commonly *fractured* at or near the median line. According to Dr. Rambaud the *line of fracture* is usually to one side of the median line, owing to the fact that the two alæ of the thyroid are

united in front by a thin median strip of cartilage at whose junction with one of the alæ the fracture occurs. *Fracture of the cricoid* is less common and more serious, as it requires more violence. *Fracture of the larynx* is dangerous on account of the liability to *dyspnoea* due to the aspiration of blood, spasm of the glottis, displacement of the fragments and oedema of the glottis. Hence in most cases *tracheotomy* should be *promptly done*. The *epiglottis*, like other elastic cartilages, is not liable to ossification but it is a favorite site for *syphilitic ulceration*.

**Excision of the larynx**, a comparatively recent operation, has been practiced a considerable number of times and almost always for malignant disease. It gives a high mortality and a poor prognosis as to recurrence. After a *preliminary tracheotomy* and exposure by a *free median incision* the larynx is freed laterally from the sternothyroid and thyrohyoid muscles and more posteriorly from the stylo- and palatopharyngei and the inferior constrictor muscles. The superior and inferior laryngeal nerves are divided, the branches of the like named arteries and the ligaments connecting the epiglottis to the tongue and hyoid bone. Then detaching it from the trachea or the thyrohyoid membrane the larynx is separated from the pharynx and œsophagus behind it, either from below up or above down, care being taken not to "button-hole" the œsophagus. Occasionally only one half of the larynx is excised.

**Laryngotomy (cricotomy)**, or the *opening* of the larynx through the *cricothyroid membrane*, is sometimes performed in place of tracheotomy on account of the ease and rapidity of its performance. It is not applicable to *children* under puberty on account of the narrowness of the *cricothyroid space*, which in the adult is at most only about one half inch in height. The *cricothyroid branches* of the *superior thyroid arteries* *anastomose across this space* and, though usually small, they occasionally cause serious and even fatal *hemorrhage*, which may be *obviated* by dividing the membrane transversely or by tearing the artery between two forceps. An objection to the operation is the proximity of the vocal cords so that it is unsuited for cases where the tube is to be worn for long. In *adults*, to whom alone the operation is applicable, it is not advisable to divide the *cricoid cartilage* to gain more room on account of the possibility of its being ossified and the little added room that it gives.

The *lymphatics* of the larynx pass to the deep cervical glands. Of the *nerves* of the larynx the *superior* supplies *sensation* to the mucosa and *motor fibers* to the *cricothyroid muscle*, which makes the cords tense. The *arytenoid muscle* is supplied both by this and the *recurrent laryngeal*, which supplies all the other muscles.

**Trachea**.—*About half* or  $2\frac{1}{4}$  inches of the trachea is *in the neck*, between the *cricoid cartilage*, opposite the *sixth cervical vertebra*, and the *episternal notch*. This *length* varies with the age, and the length and position of the neck. Thus in extension of the neck it may be increased by three fourths of an inch in its *cervical portion* and one inch (Branne) altogether, owing to its *elasticity*. This *elasticity*

allows it to accommodate itself to the movements of the neck and also causes the lower end to retract when it is severed. The retraction is favored by the loose connective tissue in which it lies and this also allows of considerable lateral mobility. This **mobility** is greater in children. It allows the trachea to escape from injury or the pressure of tumors on one side of it, and adds to the difficulties of tracheotomy. As the trachea passes somewhat backward as it descends its *upper part* is *more superficial*, hence when possible tracheotomy should be performed here, for not only is it deeper below but its relations are more complicated.

**Relations of Overlying Parts.** (Fig. 35.)—**Above the thyroid isthmus**, which lies in front of the second, third and fourth tracheal cartilages, the sternohyoid and sternothyroid muscles are separated by a slight interval and the superficial and middle layers of deep cervical fascia form practically a single layer in the median line. The levator glandulae thyroideae muscle and the pyramidal lobe of the thyroid when present lie in front of the trachea. As the *thyroid isthmus* may leave uncovered above it but a single tracheal ring it must be *retracted downward*. To permit this the *fascia* connecting it to the cricoid cartilage should be *divided* by a *transverse incision* over the latter and then its downward retraction is easy. In *children* the *thyroid isthmus* is little more than connective tissue and may be ignored or divided between two ligatures and the latter may be done in the adult. Abnormal branches of the superior thyroid artery or twigs of it to the pyramidal process, when present, may cross the upper tracheal rings, and a communicating branch between the superior thyroid veins may cross at the upper border of the isthmus.

**Below the thyroid isthmus** the superficial and middle layers of the deep cervical fascia are separated from one another by an interval filled with loose connective tissue and fat, in which there is a transverse anastomosis between the anterior jugular veins, just above the sternum. Below the thyroid gland the *superficial layer* splits into two layers attached to the anterior and posterior borders of the episternal notch and enclosing a triangular interval so that there are *three fascial layers to incise* at this level. Beneath the middle layer of the deep fascia is a layer of fatty connective tissue in which the inferior thyroid veins, the thyroidea ima, when present, and, in infants under two years of age, the upper 1 cm. of the thymus gland lies in front of the trachea. At the very root of the neck the *left innominate vein* crossing the trachea may extend up above the sternum, especially when there is venous congestion or when the neck is extended, both of which conditions are usually present when tracheotomy is performed. The *carotids* crossing the trachea antero-laterally may occasionally overlap it in front to an abnormal degree and the left common carotid when it arises from the innominate may cross the trachea above the sternum. The infrahyoid muscles are here in close contact and the trachea is more movable.

**Tracheotomy** is called **high or low** according as it is above or below the isthmus of the thyroid body. The above facts, in addition to the depth from the surface and the greater danger of broncho-pneumonia

# PLATE XI.

FIG. 34.

and of the sinking of pus into the mediastinum, make the **high operation always to be preferred**.

In either operation the neck should be *fully extended*, for this steadies the trachea, makes it more superficial, lengthens the neck and the portion of the trachea in the neck and makes tense the structures in front. The chin is held in the same longitudinal line with the episternal notch and the incision is made *exactly in the median line*. The *cervical fascia* should be well and *freely divided* to avoid the not uncommon accident of passing the tube between the fascia and the trachea. The *trachea* should be *steadied* from above by a sharp hook in the median line as a guide to the latter and to the opening when made. Cases are reported where, from lack of such precaution, the trachea has been opened from the side or behind or even through the oesophagus and where the opening when made could not be readily found again. The *opening* should be made by a thrust of the knife to insure the penetration of the lining mucosa to avoid the mistake of passing the tube into the trachea between the mucosa and the fibro-cartilaginous framework.

The *diameter* of the trachea *varies with the age* and to some extent individually and is of importance with reference to the size of the tracheotomy tube to be used. In the adult cadaver the greatest transverse diameter may vary between three quarters and one inch but in the living subject it is less. According to the observations of Symington and Guersant the following *diameters of the tube* are suited to the ages given. Under  $1\frac{1}{2}$  years, 4 mm.;  $1\frac{1}{2}$  to 2 years, 5 mm.; 2 to 4 years, 6 mm.; 4 to 8 years, 8 mm.; 8 to 12 years, 10 mm.; 12 to 15 years, 12 mm.; adults, 12 to 15 mm. The tube should not be too curved lest the pressure of its sharp end cause an ulceration into the innominate vein or artery or the common carotid and occasion a fatal hemorrhage. I have known of one such case and several are recorded.

The **difficulties of tracheotomy in children** depend upon the shortness of the neck, the small size of the trachea, its mobility and depth and the high level at which the great vessels frequently cross it. The full length of the cervical portion of the trachea in a child of 3 to 5 years is about  $1\frac{1}{2}$  inches.

The *cartilages prevent the collapse* of the tube from internal suction and external atmospheric pressure in inspiration and the pressure of enlarged thyroids and other tumors. Constant pressure, as of a large goitre, may cause the gradual absorption of the rings beneath the area of pressure, so that a long, special form of tracheal tube may be required to avoid collapse of the trachea. Ossification of the tracheal cartilages commences at about 40 to 50 years of age. In the child the trachea collapses on slight pressure, owing to the yielding character of the thin cartilaginous rings. Treves mentions a case where he saw the trachea of an infant bent on itself and invaginated into its lumen by the pilot of the tracheotomy tube.

The *musculo-membranous posterior portion* of the tracheal wall is *in contact with the oesophagus* which deviates somewhat to the left in the lower part of the neck. The absence of cartilaginous rings be-

tween the trachea and oesophagus avoids the pressure of the trachea upon the oesophagus, which might impede deglutition. Impacted foreign bodies or malignant disease in the oesophagus may cause serious difficulty in respiration by pressure on the posterior soft portion of the tracheal wall. These two tubes adhere together by loose connective tissue, allowing movements of one upon the other. The easily felt trachea is of great importance as a landmark in external oesophagotomy in the neck. In the angle between them lie the *recurrent laryngeal nerves*, the right being more behind, the left to the side of the trachea.

The *common carotid arteries*, and the other contents of their sheaths, as well as the inferior thyroid and the vertebral arteries, are near enough to be said to be in relation with the trachea *on the sides* but are not near enough to disturb the operator in tracheotomy, especially if he keeps strictly in the median line and is careful to fix the trachea by a sharp hook in that line. In a low tracheotomy the great vessels are nearer the sides of the trachea than they are above where the lobes of the thyroid gland intervene.

**Foreign bodies** in the trachea are usually *arrested* at its *bifurcation* and if they pass beyond this it is into the right bronchus as a rule (see p. 223). They entail a fatal result unless removed by coughing or by operation. Through a *low tracheotomy* they can sometimes be reached and removed by a long forceps as low down as the bifurcation, but more often they are expelled by a violent fit of coughing, through the wound or through the glottis, at the time of operation or subsequently.

**High tracheotomy** is not infrequently done as a *preliminary operation* in several operations about the mouth and neck. Its *object* is usually to prevent blood entering the trachea and for this purpose the trachea is plugged around the tube by one of the several tampon canulae or by small pieces of sponge or gauze. In every tracheotomy a slight amount of blood enters the trachea when it is opened, but if it merely comes from a venous oozing the latter soon ceases when the air rushes into the lungs and the right heart is allowed to empty itself.

The real *surgical limit of the trachea* is the episternal notch; the thoracic part of the trachea is described among the contents of the thorax as is also the entire oesophagus.

**The Thyroid Gland.** (Fig. 35.)—Its *lateral lobes* extend from the fifth or sixth tracheal rings, three fourths of an inch above the sternum, up to the middle of the thyroid cartilage. Their greatest *dimensions* are normally about 2 inches in length,  $1\frac{1}{4}$  inch in breadth and  $\frac{3}{4}$  inch in thickness. When the lobes distinctly exceed these measurements they may be considered to be *enlarged*. They may be temporarily enlarged in menstruation. In infancy and in females they are relatively larger than in adults and in males respectively and the right lobe is also commonly larger than the left. It is also noticeable that thyroid enlargements (*goitre, bronchocele*) are more common in females and on the right side. The size of the gland commonly diminishes in late life.

The *isthmus* varies from one fourth to three fourth inches in *height*.

and lies in front of the second, third and fourth tracheal rings, but it may extend up to the cricoid and sometimes nearly down to the sternum. In infants it is but slightly developed, which is of advantage in tracheotomy. From its upper margin, or the adjacent margin of the left lobe, springs the *pyramidal lobe* when present, as it is in about four fifths of all cases (Streckeisen). This represents a remnant of the thyroglossal duct which in the foetus extends upward from the isthmus behind the hyoid bone to the foramen cæcum on the tongue and from which the isthmus is developed. This duct occasionally remains open and from it are developed the *accessory thyroids*, not infrequently found in the neighborhood of the hyoid bone. Other accessory portions of the thyroid, originating as separated portions of the main lobes, may occur from the region of the aortic arch to the hyoid bone. These may be the origin of "*accessory goitres*" which cause difficulty in diagnosis and removal, as they are likely to be very movable, slipping readily into the mediastinum. Deeply seated carcinoma of the neck may also have its origin in them.

The relations of the thyroid are of great importance in reference to the symptoms of its enlargement and the operation of excision or enucleation of such enlargements. It is covered in front by the sterno-hyoid, sternothyroid, and omohyoid muscles and overlapped by the anterior border of the sternomastoid. It lies beneath the superficial and middle layers of the deep cervical fascia. It is enclosed by a fibrous capsule from whose inner and posterior parts two broad bands, the *suspensory ligaments*, are continued upward and attached to the cricoid cartilage. It is this attachment which is divided in tracheotomy to allow the downward retraction of the isthmus. This fibrous capsule is to be opened in excision of the gland. The thyroid is moulded to the underlying trachea and larynx and is attached to them by fibrous tissue, where it is in contact, as well as by the suspensory ligament. Hence it moves with them in deglutition, an important point in the diagnosis of bronchocele from other cervical tumors.

The enlarged thyroid may compress the trachea, especially if the enlargement is rapidly formed, for it is held down by the overlying muscles. Hence to relieve the dyspnœa the division of these muscles or of the isthmus has been practiced, but often with unsatisfactory results. In chronic enlargement the pressure may cause erosion of the tracheal rings and collapse of the trachea. When the enlargement is unilateral the mobile trachea may escape pressure by being pushed to the opposite side. Those tumors cause the most marked pressure symptoms which, developed from the lower end of the gland or from an accessory gland, lie between the trachea and the sternum.

The thick posterior border is in contact with the *carotid sheath* and is grooved by the common carotid artery. A large goitre may press the great vessels outward, it may cause congestion of the face and head by pressure on the internal jugular and, by adhering to the latter, it may add to the difficulties of excision. On account of its contact with the carotid the enlarged thyroid may receive pulsation from it and if

a unilateral thyroid tumor is soft and vascular the resemblance to aneurism is still closer, especially when a thrill or bruit is produced, as may be the case. The pressure on the carotid and internal jugular may disturb the cerebral circulation. The thyroid also is in contact with the lower part of the *pharynx* and with the *œsophagus*, especially on the left side, and when enlarged may cause dysphagia.

The relation to the **recurrent laryngeal nerves** is of the utmost importance, as pressure on them may lead to their paralysis and the resulting alteration or loss of voice, and they are also in danger of being injured in excision of the thyroid. The left recurrent nerve is more exposed to pressure for it lies more external to and less behind the trachea. The recurrent nerves are in danger of being injured in the *ligation of the inferior thyroid artery*, being most often found in front of or behind the two branches of this artery, near the point of bifurcation. Hence the artery is tied only once, carefully, and severed close to its entrance on the postero-inferior aspect of the gland. The *sympathetic nerve* is also in close relation to the trunk of this artery, usually embracing it, and the middle cervical ganglion is in contact with it. As the gland is supplied by branches from this ganglion the latter has been removed for the cure of exophthalmic goitre.

Relatively to the volume of the gland the *arteries, superior, inferior* and, when present, the *thyroidea ima*, are of large size, so that the gland is one of the *most vascular* of organs. There is but little arterial anastomosis between the two sides along the isthmus, but a branch to the pyramidal lobe from the superior thyroid may cross the upper end of the trachea and be in the way in tracheotomy. The *four arteries* are situated at the *four angles* or poles of the two lobes and run some little distance on the posterior surface before entering the gland. The *inferior thyroid artery* passes in front of the vertebral and behind the common carotid a little below the transverse process of the sixth cervical vertebra. There is usually a *venous anastomosis* just above and below the isthmus; the former is between the superior veins, the latter is the starting point for the inferior thyroid veins. The superior veins cross the external or common carotid, the inferior threaten the operator on either side of the wound in a low tracheotomy. The middle veins cross the common carotid about where the omohyoid crosses it.

**The function** of the gland, still imperfectly understood, concerns the manufacture of the blood (especially as to its chemical composition), the regulation of the blood supply of the head (especially the brain) and the control of mucinoid substances. It also has important *internal secretory properties*. Its atrophy, destruction or complete removal, or the degenerated goitrous condition met with in cretins, is likely to lead to **myxœdema**, a condition in which a mucinoid substance is deposited in the subcutaneous tissues, especially in the eyelids, lips and hands. Hence the entire gland should never be removed for a simple goitre. Cretinism is also associated with idiocy.

The most important **pathological changes** involving the thyroid consist in an **enlargement** of a part or the whole of the gland, known as

## PLATE XII.

*goître, bronchocele* or struma. This enlargement may involve all the elements nearly equally or either the parenchyma, the fibrous or vascular elements more especially. Thus we may have soft parenchymatous goîtres, often with one or more cysts from enlarged vesicles, hard fibrous goîtres and again soft vascular goîtres. The latter are associated with exophthalmos and tachycardia in *exophthalmic goître*. The latter form may be due to an abnormality of the inhibitory fibers from the middle cervical sympathetic ganglion, which supply the vessels of the thyroid, hence this ganglion has been removed to cure the goître. For this and the other forms of goître, especially when they cause disturbance from pressure, *excision, enucleating excision, or enucleation* is done. One side only is usually operated on in excision, but in the latter two forms of operation, where part of the gland is left, both sides may be dealt with.

In Kocher's method of *excision* the *incision* begins over the sternomastoid at the level of the thyroid cartilage, runs internally in the line of the cutaneous folds to the median line and then follows the latter to the sternum. A *flap* is turned back *after dividing* the skin, subcutaneous tissue, platysma, anterior jugular vein, a branch to this from the facial vein along the anterior border of the sternomastoid and a transverse anastomosis between the two anterior jugulars at the bottom of the neck. After dividing the superficial and middle layers of the cervical fascia in the median line between the infrahyoid muscles, the sternohyoid and sternothyroid muscles are partly, or wholly, divided at their upper ends. The *capsule* of the gland is then opened. It is the *veins*, often distended from the dyspnoea which the patient suffers, that give the principal trouble, and large accessory thin-walled veins are often met with in large goîtres. When the veins are tied and divided so as to get beneath the tumor its superior vessels are cut between two ligatures at the upper pole, the inferior thyroid artery cautiously ligated and its branches cut where they enter the gland, the inferior thyroid veins cut between two ligatures, the gland enucleated from below or above and the isthmus divided after being ligated. The *enucleating excision*, in which the inner part of the lobe is left, avoids the danger of injuring the recurrent laryngeal nerve which is sometimes separated from the gland with difficulty.

The **deep cervical fascia** (Figs. 36, 37 and 38) is of considerable surgical importance but its description differs with almost every writer on the subject, owing in part to the individual differences met with in almost every case. In general three layers may be described below the hyoid bone. The **superficial layer** splits to enclose the sternomastoid and trapezius muscles in a sheath. This layer on the two sides unites anteriorly in the median line and posteriorly with the ligamentum nuchæ, thus forming a complete investment of the neck. Below it is attached to the sternum, clavicle and the acromion and spinous processes of the scapula. In the *anterior median line*, below the thyroid gland, this layer *splits* into *two divisions* attached to the anterior and posterior border of the episternal notch. Between these two divisions

is a triangular space, continuous with the space between the two layers of the sheath of the sternal head of the sternomastoid, and containing cellular and adipose tissue and one or two small lymph nodes (Paulet). *Above the hyoid bone* it splits to form a *sheath* for the *submaxillary gland* which is attached to the lower border of the jaw. *Above this* it is continuous with the *parotid* and *masseteric fascia*. From the anterior border of the sternomastoid sheath a prolongation passes forward to the angle of the jaw which separates the sheath of the submaxillary from that of the parotid gland and is continued to the styloid process as the *stylomaxillary ligament*.

The middle layer is attached to the hyoid bone, covers the muscles above it which form the floor of the submaxillary triangle, and is attached to the mylohyoid ridge. Below the hyoid it forms a *sheath* for the sternohyoid, sternothyroid and omohyoid muscles. In the *median line*, in the interval between these muscles, the fascia of the two sides joins together and with the superficial layer, forming a kind of *linea alba* of the neck in the line of median incision. *Laterally* this layer is said by some to reach only as far as the limit of the omohyoid, which it ensheathes, and by others to join the superficial layer at or near the posterior border of the sternomastoid. *Inferiorly* it is attached to the posterior border of the episternal notch and sends an expansion around the left brachiocephalic vein, which is continuous with the fibrous layer of the *pericardium*. More laterally it is attached to the postero-superior border of the clavicle, whence it sends an expansion around the great veins behind it (*subclavian* and *internal jugular*). Thence it passes to the sheath of the *subclavius* muscle and from the latter is continuous with the *clavipectoral fascia* (*costocoracoid membrane*) and the sheath of the axillary vessels.

From the *deep surface* of this layer are given off cellular *expansions* which surround in a sheath-like manner the *trachea*, *thyroid body* and *carotid vessels* but do not deserve the name of *fascia*, although sometimes described as a distinct "tracheal layer." The "*suspensory ligament*" of the thyroid gland, attaching it to the *erlicoid cartilage*, is derived from this expansion. According to Merkel the *carotid sheath* is made up of loose connective tissue and does not deserve the name of *sheath*.

The **deep or prevertebral layer** covers the prevertebral muscles and is attached *laterally* to the cervical transverse processes, where it is continuous with the sheath of the *scalenus anticus* muscle and of the *brachial plexus*. Thence it passes outward to join the superficial layer. *Inferiorly* it is continuous with the sheath of the *subclavian* and *axillary vessels*. According to some it completes the carotid sheath posteriorly. It lies behind the *œsophagus* and *pharynx*.

The *occipital*, *superior carotid* and *submaxillary triangles* are roofed over by the *superficial layer*; the *subclavian* and *inferior carotid triangles* by the *superficial* and *middle layers*. The layers as thus described bound certain *spaces* and the great practical importance of this *fascia* consists in its tendency to *limit* the growth of cervical

tumors and the course of cervical abscesses. This limitation is by no means absolute, for abscesses often break through fascial planes. Cold abscesses are more likely to be guided by fascial planes than those due to an acute inflammation.

Between the *superficial fascia* and the *superficial layer* of the deep fascia lies the external jugular vein, the platysma and loose tissue. Abscess here perforates externally and so does one between the superficial and middle layers, as the superficial layer is generally thin and offers little resistance to pus. Abscess between the superficial and middle layer is prevented from descending into the mediastinum and axilla by the attachment of the middle layer to the sternum and clavicle. Suppuration is more common here than elsewhere in the neck. This compartment contains the anterior jugular veins, loose connective tissue and lymphatic nodes.

Abscess in the *third compartment*, that between the middle and deep layers, can not reach the surface without perforating the two overlying layers, hence unless promptly relieved it is likely to extend down into the *mediastinum or axilla*, with which this space is continuous, depending for its course upon whether the abscess is situated mesially or laterally. Mesially they follow the loose tissue around the trachea and oesophagus, as after operations on the base of the tongue, the larynx, trachea, thyroid or oesophagus. As this compartment also contains the most important structures of the neck, the trachea, oesophagus, thyroid gland, carotid artery, and the accompanying vein, nerves and lymph nodes, an abscess may exert a serious pressure upon these structures. For these two reasons an *early incision* in such deep abscesses of the neck is imperative. Owing to the lack of it such abscesses have burst into the trachea or oesophagus and even into the pleura. Occasionally they have opened into the great vessels as in a remarkable case reported by Mr. Sarony, where a considerable part of the common carotid, a still larger part of the internal jugular vein and a large part of the vagus nerve were destroyed (Treves). Such cases depend upon the unyielding character of the cervical fascia.

In the *fourth compartment* an abscess is known as *prevertebral*, or *retropharyngeal*, if above the lower limit of the pharynx. The latter form may be opened through the mouth or from the side of the neck and if unrelieved may gravitate down into the mediastinum. Laterally these deep abscesses may follow the brachial plexus to the posterior triangle or even to the axilla. In general then superficial abscesses, or those external to the middle layer, are comparatively safe, showing a tendency to perforate and open externally; deep abscesses, or those beneath the middle layer, are dangerous from pressure or the liability to extend into the mediastinum and should be relieved by incision as promptly as possible.

As the cervical fascia gives a sheath to the large veins that perforate it and are in contact with it and attaches them closely to the adjacent bones and muscles they are thereby held patent and ready for the free flow of blood from the head and neck and at the same time they are

liable to gape when wounded, so as to admit air. Hence they should always be ligated before division. According to some the cervical fascia, by reason of its firmness and its attachment to bones above and below, supports the soft parts of the neck and helps them to *resist atmospheric pressure* in inspiration, as first pointed out by Allan Burns.

The lymphatic nodes (Fig. 39) of the neck receive the *lymphatics* of the *head and face* and are liable to become *enlarged* in the course of the various septic, tubercular, syphilitic and cancerous affections of the parts from which their lymphatics come. Among enlarged lymph nodes of the neck *lymphadenoma* of tubercular origin is a very common condition and forms the majority of tumors of the neck, the source of infection being usually the upper air passages (nose, nasopharynx, pharynx and tonsils). The breaking down of enlarged cervical nodes is a common cause of abscess of the neck. It follows that it is important to have a clear idea of the sources from which the several groups of nodes are supplied both to aid in the diagnosis of the primary lesion and in order to know where to look for lymphatic involvement in any given lesion.

The **suboccipital nodes**, just below the posterior attachment of the occipito-frontalis, receive lymph from the back part of the scalp and are frequently enlarged in secondary syphilitic eruptions of this part. The **mastoid nodes**, just over the insertion of the sternomastoid, and the **parotid nodes**, on and in the parotid gland, receive the lymph from the middle and anterior part of the scalp respectively. The parotid nodes also receive lymphatics from the cheek, outer parts of the lids, all of the parts within the cranium, and the postpharyngeal nodes. For the latter as a focus for postpharyngeal abscess see p. 114. The **submaxillary nodes**, under the sheath of the submaxillary gland in the digastric triangle, form a chain below the jaw. Their tributaries come from the salivary glands, lips, floor of the mouth, fore part of the tongue, nose and frontal region. The one or two median **suprahyoid nodes**, on the mylohyoid and between the anterior bellies of the digastric, receive lymphatics from the middle of the lower lip and the chin. The deeper **internal maxillary group** at the sides of the fore part of the pharynx receive lymph from the orbit, the palate, the greater part of the nasal cavity, the upper jaw, the deep surface of the cheek, the back part of the tongue and the greater part of the pharynx.

The above nodes empty into the superficial and deep cervical groups. The **superficial cervical nodes** (4-6) lie along the external jugular vein, between the platysma and deep fascia, and receive lymphatics from the suboccipital, mastoid and submaxillary nodes, the ear and the surface of the neck. Those in the subclavian triangle communicate with the axillary nodes and hence may be enlarged in carcinoma of the breast. On account of their communication with the lymphatics of the oesophagus the enlargement of these supraclavicular lymph nodes in cancer of the stomach is regarded by Virchow and others as of diagnostic value, though it is unusual. The **deep cervical nodes** accom-

PLATE XIV.

FIG. 39.

Diagram of the lymph-nodes and vessels of the head and neck, showing the regions which are drained into each group of nodes. Deep structures in red, superficial in black. (F. H. Gerrish.)

pany the internal jugular vein and are arranged in *two sets*, the upper about and above the bifurcation of the carotid and the lower set below. They receive all the lymphatics of the head and neck directly or indirectly by receiving the lymphatics from the superficial set and those from the other groups which do not empty wholly into the latter. At the base of the neck they communicate with the mediastinal, subclavian and axillary nodes.

Of the deep set the nodes near the bifurcation of the carotid often first show enlargement, but in most cases where the nodes are exposed by operation many more are involved than expected and a chain of glands, gradually decreasing in size, leads from the position of the visible tumor. Therefore in removing cervical *lymphadenoma* the operation often proves more extensive and formidable than expected. They may be considerably enlarged without detection by palpation and we often feel them without suspecting their real size or numbers. In removing them their *relation* to the *internal jugular vein* is of great importance, as they may be adherent to it and difficult to separate from it, especially when involved secondarily to cancer. With the exception of a few, like the superficial cervical group, the cervical lymph nodes lie beneath the deep fascia. They may also be enlarged in the rare cases of *lymphosarcoma* and the peculiar affection known as *Hodgkin's disease*. Although in most cases of involvement of the lymph nodes the infection comes from the same side of the body as the enlargement, yet in exceptional cases it comes from the opposite side. Thus exceptionally when one side of the tongue is the seat of epithelioma the opposite submaxillary nodes are involved.

**Embryologically** the neck is formed by the coalescence of five visceral or branchial arches separated by four furrows or **branchial clefts**. These clefts, seen on the surface, correspond to a like number of *inner clefts* or pharyngeal pouches on the walls of the pharynx, separated from the outer clefts by a thin *closing membrane*, composed of a layer of entoderm and one of ectoderm. Of these arches and clefts the **first arch** forms the lower and upper jaws, the incus and the malleus; the **second** the stapes, the styloid process, the stylohyoid ligament and the lesser cornu of the hyoid bone; the **third** forms the body and great cornu of the hyoid; the fourth and fifth form no special structures. The **first outer cleft** forms the external ear, the corresponding **inner cleft** the middle ear and Eustachian tube and the **closing membrane** between them forms the membrana tympani. The **fourth inner cleft** forms the lateral lobes of the thyroid gland and the tissues adjacent to the **second cleft** take part in forming the posterior third of the tongue and the middle portion (*isthmus*) of the thyroid gland.

If the lower branchial arches do not fuse together, as they normally should in the second month of foetal life, the corresponding cleft remains partly open as a so-called **branchial fistula**. These may be lateral or median in position and complete or incomplete. In the case of *complete fistulae* the closing membrane gives way and there is a narrow canal lined by mucous membrane, leading from without back-

ward, inward and upward for  $1\frac{1}{2}$  to  $2\frac{1}{2}$  inches. The *internal opening* of such a fistula is in the lower part of the pharynx or in the posterior palatine arch near the tonsil. The *external opening* varies in position according to the cleft which remains open, being most often near the sternoclavicular joint, in the region of the fourth cleft, or at the anterior or posterior border of the sternomastoid near the larynx, in the second or third cleft. *Incomplete fistulæ* open either externally or internally in the same position as one end of a complete fistula. Near the external opening of a fistula, or in spots where they commonly open, a protruding fold of skin may be found and above it a cartilaginous mass is sometimes to be felt. As the external ear is formed by the fusion of six similar nodules at the outer end of the first visceral cleft, the more prominent of these are called *supernumerary auricles*. Median fistulæ of the neck, or tracheal fistulæ, are rare and if incomplete and internal may give rise to air tumors. *Congenital diverticula of the œsophagus* are probably always incomplete lateral branchial fistulæ of the neck.

From obstruction of the external or internal opening of a fistula or from a portion of the wall of the cleft shut in by the closure of the arches, dermoid and **branchiogenic cysts** may be formed. Such shut-in portions of the epithelial tissue may be the nucleus of the rare primary carcinomas of the neck.

## CHAPTER II.

### THE UPPER EXTREMITY.

THE upper extremity, *the organ of prehension and touch*, is notable for its mobility, which is due to the freedom of movement of its joints and its many muscles. Its only bony connection with the skeleton of the trunk is through the clavicle.

In the upright position the upper extremity reaches to the middle of the thigh, the right being stronger and  $\frac{1}{2}$ –1 cm. longer as a rule. The greater development of the right upper extremity depends, according to Hyrtl, on the arrangement of the blood supply which is more abundant and comes more directly from the heart on the right side. The anomalous origin of the right subclavian as the last branch of the aortic arch is associated, according to the same author, with left-handedness and the greater development of that side.

### THE REGION OF THE SHOULDER.

This comprises the upper part of the extremity and reaches down to the insertion of the pectoralis major and latissimus dorsi muscles.

**Surface Landmarks and Markings.**—The clavicle, acromion process and spine of the scapula can be readily *felt subcutaneously*.—The clavicle is not quite horizontal, but inclines slightly upward at its outer end in the erect position and even more so in the reclining position when the weight of the arm no longer pulls it down. The *upper surface* is only covered by skin and platysma and the anterior and posterior surfaces are more or less readily palpable. The *deltoid tubercle* of this bone may be felt if large and may even be mistaken for an exostosis. The *sternal end* is large and prominent especially in muscular subjects and the outer or *acromial end* is often enlarged and projects above the level of the acromion so that it should not be mistaken for a dislocation at the acromioclavicular joint. The latter joint is in the vertical line passing up the middle of the arm anteriorly. The angular prominence which can be felt externally at the junction of the *acromion* and the spine of the scapula is the best point from which to *measure the arm* down to the external condyle. The latter point, the tip of the acromion and the radial styloid process are all in the same line when the arm hangs at the side and the palm looks forward.

When the arm hangs at the side the *upper angle* of the *scapula* corresponds to the upper border of the second rib, the *lower angle* to the seventh intercostal space and the *vertebral end* of the *spine of the scapula* to the third intercostal space, to the interval between the third and

fourth thoracic spines and to the fissure between the upper and lower lobes of the lung.

The *vertebral border* of the scapula may be made prominent by carrying the hand as far as possible over the opposite shoulder, the *axillary border* and inferior angle by placing the forearm behind the back.

The *prominence of the shoulder* is due to the acromion process, but the *roundness* just below this depends upon the prominent great tuberosity of the humerus covered by the deltoid muscle. Hence this roundness gives way to a flattening when the underlying bony bolster is removed, as in a dislocation of the shoulder, or is diminished in bulk, as in an impacted fracture of the anatomical neck. The *head of the humerus* can be felt high up in the axilla, especially when the arm is abducted, which brings the head in contact with the lower part of the joint capsule. The lower margin of the *glenoid cavity* can also be felt high up in the axilla below and internal to the humeral head. The *head and internal condyle* of the humerus and the styloid process of the ulna are in the *same line*. This relation of the head and internal condyle, being constant in all positions of the arm, is of value in the diagnosis of injuries about the shoulder and in reducing dislocations. In thin subjects the two *tuberosities* of the humerus and the *bicipital groove* between them can be felt beneath the deltoid, especially on rotating the humerus. The bicipital groove looks directly forward when the arm hangs at the side with the palm of the hand looking forward.

The groove between the deltoid and pectoralis major, distinguishable in most cases, contains the *cephalic vein* and, more deeply, the humeral branch of the acromiothoracic artery. The upper end of this groove widens out into a triangular *infraclavicular fossa*, the base of the triangle being formed by the clavicle. On deep pressure here the *coracoid process* can be felt just beneath the margin of the deltoid and a little below the clavicle. The depression of the infraclavicular fossa is obliterated in subcoracoid dislocations of the humerus, in some fractures of the clavicle with displacement, in some axillary tumors, in lymphatic enlargements and in inflammations along the upper part of the axillary artery. It is replaced by a prominence in intracoracoid dislocations of the humerus. If the muscles are relaxed we may detect the pulsation of the *axillary artery* by pressure in the infraclavicular fossa below the middle of the clavicle and we may also compress the artery against the second rib. By a vertical incision through the center of the *coracoacromial ligament* the shoulder joint is opened and the biceps tendon is encountered. Hence in resection of the shoulder joint the coracoid process is a landmark for the incision.

The *anterior border of the axilla* is formed by the *lower margin* of the *great pectoral muscle* which passes from the sixth costal cartilage to the outer bicipital ridge and nearly follows the line of the fifth rib. The anterior and posterior axillary borders are well marked, especially when the arm is abducted to an angle of about  $45^{\circ}$  and the muscles forming these borders are contracted, in which position the *depression of the*

*axilla* is deepest. As the arm is raised to and above the horizontal line the axillary depression becomes shallower by reason of the projection into it of the humeral head, the approximation of the anterior and posterior axillary folds and the projection of the coracobrachialis muscle along the humeral side of the axilla. When the arm is brought nearly to the side the thoracic wall bounding the axilla internally can be explored as high up as the third rib. The *axillary lymph nodes* on this or on the outer side cannot be felt unless they are enlarged.

**Topography of Some of the Deeper Parts.**—When the arm is abducted the course of the *axillary artery* is represented by a line from the center of the clavicle to the groove along the inner border of the *coracobrachialis muscle*. The latter muscle comes well into view when the humerus is rotated a little outward.

The position of the *pectoralis minor* muscle is outlined, by two lines, converging from the upper border of the third and the lower border of the fifth rib, just external to their cartilages, to the coracoid process. The position of the *acromiothoracic artery* is indicated by the point where the upper line crosses the course of the axillary artery and the *long thoracic artery* runs in the lower line. When the arm hangs at the side the *circumflex nerve* and *posterior circumflex artery* wind around the humerus under the deltoid about a finger's breadth above the center of the vertical axis of the latter. A finger's breadth below this point the *dorsalis scapulae artery* crosses the axillary border of the scapula.

For convenience of study we may divide the shoulder into four regions. (1) The anterior or clavicular region; (2) the posterior or scapular region; (3) the outer or deltoid region (including the shoulder joint); (4) the axilla.

### 1. The Anterior Region of the Shoulder.

This is also called the *clavicular region* because the clavicle forms its bony framework. The skin over this region is loosely attached and hence freely movable, a fact which explains why it usually escapes being wounded in contusions and which partly accounts for the rare occurrence of penetration in fractures of the clavicle. It must also be carefully put on the stretch in the incision for subclavicular ligation of the axillary artery. The *supraclavicular nerves*, the cutaneous nerves of this region, in their passage in front of the middle third of the clavicle are liable to contusion, and such an injury explains the occasional severe pain after blows on the clavicle. According to Tillaux the severe pain which occasionally persists after fractures of the clavicle is due to the involvement of these nerves in the callus.

**Fracture of the clavicle** is one of the commonest forms of fractures, a fact due to its superficial position, its slender form and the circumstance that it receives a large share of almost all shocks which involve the upper extremity. Such fractures are more often due to indirect than to direct violence. Among the indirect fractures the

great majority are at the *outer end of the middle third* (*i. e.*, the middle two inches) of the bone, for the reason that this is the most slender and most sharply curved part and also the meeting point of the two curves and of the more fixed outer third with the more movable inner two thirds. In this connection it may be noted that the clavicle breaks in such cases by the exaggeration of its normal curves.

The **direction** of the fracture is accordingly usually obliquely inward, downward and backward. As to the **displacement** that occurs it should be borne in mind that the clavicle serves as a kind of *outrigger* to hold the shoulder and upper extremity away from the thorax. When this support is broken the shoulder with the outer fragment is naturally displaced inward and sinks downward by its own weight. The inward displacement also causes the shoulder to *swing forward* so that the common displacement of the inner end of the *outer fragment* is *downward, inward and forward*. The outer end of the outer fragment is also *rotated forwards*. This *outrigger* action of the clavicle may be illustrated by a bar supporting a sign from a building, the outer end of the bar being also supported by a chain from a point higher up on the wall, the chain representing the trapezius, etc. If the bar breaks the outer end with the sign falls downwards and inwards. But this is not the only and perhaps not the most important *cause of the displacement*; the other causes being the continuance of the force producing the fracture, the direction of the fracture and the action of the muscles. Thus in transverse fractures there may be no such displacement, but instead of it an upward angle, due to the sinking of the shoulder, or no displacement at all, especially in green-stick fractures. Again if the oblique direction is much inclined backward the inner end of the outer fragment may be forced behind or simply below the inner fragment and not in front of it. Among the *muscles* the *pectoralis* and *latissimus dorsi* pull the outer fragment inward and downward. The outer end of the outer fragment is rotated forward by the pectorals and the serratus magnus. The *inner fragment*, if displaced at all, is pushed up by the outer fragment beneath it, rather than pulled up by the sternomastoid.

Owing to the inward displacement of the outer fragment causing the fragments to overlap, there is necessarily a considerable *shortening* which may nearly equal in extreme cases one third the length of the bone, or two inches. As this shortening is difficult to remedy completely it follows that some shortening remains permanently after fracture of the clavicle more often than after any other fracture save that of the femur. This shortening causes some narrowing and rounding of the affected shoulder.

It follows from the nature of the displacement that **reduction** is to be obtained and maintained by carrying the shoulder upward, outward and backward. Upward pressure on the elbow carries the shoulder upward and, with a pad in the axilla as a fulcrum and the arm as a lever, inward pressure at the elbow forces the shoulder outward. Some shortening and *deformity* usually *persists* and any forward dis-

placement of the outer fragment may be particularly hard to keep reduced unless the patient is willing to lie perfectly flat on the back for three weeks or so. In this *recumbent position* the weight of the arm no longer drags the shoulder downward and the weight of the shoulder and the pressure of the body on the scapula, forcing its outer border outward and backward, pull the outer fragment outward and backward better than any form of bandage. The mobility of the clavicle and the number of strong muscles attached to it explain the difficulty of applying a satisfactory fixed dressing and the tendency of the callus to become excessive. In *fracture of the outer third*, which is more often transverse than oblique, there may be *no displacement or an angular one* due to the forward and inward turning of the outer fragment.

The clavicle may be **broken by muscular violence**, probably by the clavicular fibers of the *pectoralis major* and *deltoid*. These tend to draw the clavicle downward and forward, in which position the outer fragment is displaced in such cases. These fractures are most often in the *middle third*. Violent movements of the limb forward and inward or upward appear to be the commonest cause. Occasionally the fracture is due to a sudden depression of the arm by which the clavicle is bent over the first rib. Fractures by **direct violence** are most apt to be *transverse* and may occur at any point, but most frequently at the *middle or outer third*.

**Green-stick fracture**, or fracture without rupture of the periosteum and hence without much displacement, occurs more often in the clavicle than in any other bone. This is partly due to the fact that such fractures occur in childhood and more than half the fractures of the clavicle are said to occur before the age of five. According to Krönlein fracture of the clavicle in children takes the place of dislocation of the shoulder by direct violence later in life. The *periosteum* at this age is also very *thick and loosely attached*. Notwithstanding the absence of deformity, and the failure of diagnosis that may result, the callus is often excessive, owing to the stripping up of the active periosteum.

The *firmness of the periosteum*, but especially the presence beneath the clavicle of the *subclavius muscle* enveloped in a dense fascia, are largely accountable for the *rare occurrence* of the **complications** of fractures of the clavicle, which consist of injuries to the vessels, nerves and lung. Although the vessels and nerves lie beneath the clavicle in the angular interval between it and the first rib in the following order from within out, subclavian vein, artery and brachial plexus, *injury to the artery* is not recorded, unless of such a nature as to produce subsequent aneurism, and only a few cases of injury to the vein and brachial plexus are on record. The *vein* from its position, as the most internal of these structures in the acute angle between the clavicle and the first rib, and from its slighter resistance is likely to be the first to be compressed. Injury to the *internal jugular vein*, lying behind the clavicle, has also been recorded. I have recently seen a case of paralysis of

the arm following a fall on the shoulder where the *brachial plexus* was found reduced to a mass of connective tissue, apparently from compression by the clavicle, though no fracture of the clavicle resulted. *Injury to the lung* by a fragment of the clavicle, as evidenced by *emphysema*, has been observed in a few cases and in other cases the emphysema was apparently due to a wound of the soft parts.

The interposed pad of the *subclavius muscle* is of great service in *resection* of the clavicle, rendering the operation easy in the outer two thirds while *behind the sternal third* are the innominate or left carotid artery, the brachiocephalic and internal jugular veins, the vagus, recurrent and phrenic nerves, the thoracic duct and the trachea. A little *more externally* the external jugular vein, the suprascapular vessels and the apex of the lung lie *behind the clavicle*. In case of *enlargement* of the clavicle the resection of its inner third may be a matter of considerable difficulty, though in case of necrosis with thickening of the periosteum the operation may be extremely easy. In any excision of the clavicle the operation is rendered much easier and safer if it can be done *subperiosteally*. The *restoration of the clavicle* after subperiosteal resection is sometimes very complete, but even when no new bone forms the removal of the entire clavicle is followed by far less alteration in position and impairment of motion of the shoulder than would be expected from its function as a support and outrigger for the shoulder. So striking is this in some cases as to lead one to question whether the displacement in fracture of the clavicle is not mostly due to the other factors, *i. e.*, continuation of the force producing the fracture, muscular action, and the direction of the fracture.

**Avulsion** of the entire upper extremity has occurred in a number of cases, especially in machine accidents. Apart from the sternoclavicular articulation only muscles hold the upper extremity to the trunk and if the clavicle is fractured only the rupture of muscles, vessels and nerves is necessary in avulsion.

**The Sternoclavicular Joint.**—The lack of adaptability between the bony surfaces forming this joint accounts largely for the amount of motion that occurs here. When the arm hangs at the side the clavicle is in contact with the socket only at its lower angle, rendering the cavity V-shaped. This allows the elevation of the shoulder in which position the bones are in more immediate contact. Accordingly in disease of this joint the motion of elevation of the shoulder is that which produces the most pain.

**Dislocation of the clavicle from the sternum** is *rare* on account of the strength of the ligaments that bind them together. It may be *complete* or *incomplete* and occurs in the (1) forward, (2) backward and (3) upward direction, in the order of frequency. The relative frequency of these three varieties depends upon the relative strength of the ligaments that resist them and that restrict the movements of the joint. Thus **dislocation forward** is *resisted* by the posterior and anterior ligaments and the weakness of the latter serves partly to explain the relative frequency of the forward dislocation. The head of the

bone, *displaced* forward and usually inward and downward, *rests on* the manubrium and carries with it the sternomastoid muscle.

**Dislocation backward** is *resisted* by the same ligaments and in addition the strong rhomboid ligament. It may be due to direct or indirect violence, more often the latter, the force pressing the shoulder forward and inward. The *head* of the bone, *lying* behind the sternum and probably between it and the sternothyroid muscle, frequently *presses* upon the trachea causing dyspnoea, less often upon the oesophagus causing dysphagia. In the region occupied by the displaced head of the bone are most important vessels and nerves, but the cases recorded show no serious pressure upon them. The head of the bone has been excised in one case to relieve troublesome dysphagia. In *complete dislocations* either forward or backward the head of the clavicle is usually also *displaced* downward and in all complete dislocations it is as a rule displaced inward also.

In addition to the ligaments resisting backward dislocation, **dislocation upward** is *resisted* by the interclavicular ligament and the interarticular cartilage; hence the rarity of this form, which implies a tearing of all the ligaments. It is usually *due to* forcible depression of the shoulder, the first rib acting as a fulcrum so that the inner portion of the clavicle is elevated. The violence continuing forces the head inward and upward behind the sternal portion of the sternomastoid. The lack of adaptability of the joint surfaces serves to explain the *ease of reduction* and the *difficulty of retention* in most cases of luxation in this joint. The recumbent position and various forms of dressing which act on the clavicle through the shoulder, as in fracture of the clavicle, have been employed. In connection with these the *injection* of 50 per cent. alcohol, or a similar fluid, with the object of producing a mass of connective tissue around the joint as a sort of new capsule, has occasionally been found useful.

The *sternoclaicularly joint* is *liable* to the ordinary *diseases of joints* and, according to some, is more often involved in pyæmia than other joints. As the synovial sac is divided into two by the interarticular cartilage, disease may commence in and be limited to one sac, but as a rule the entire joint (both sacs) become involved. Owing to the fact that the *anterior sternoclavicular ligament* is the *thinnest and weakest part* of the capsule *swelling* is as a rule first evident in front and, when *spontaneous perforation* occurs, the pus usually escapes anteriorly. If, as may happen, it escapes through the posterior ligament it may readily reach the mediastinum. The notable fact that the disease of this joint never results in ankylosis is due chiefly to the entire lack of adaptability of the two bony surfaces and, to a less extent, to the constant slight movement here and the occasional persistence of the interarticular cartilage. The *importance* of bearing in mind the *relations* of this joint to the great vessels behind it is illustrated by a case reported by Hilton in which a large abscess in the joint received pulsation from the subjacent subclavian or innominate artery and was first thought to be an aneurism.

The acromioclavicular joint depends for its *strength* upon its *ligaments*, for its shallow flat *joint surfaces* are beveled from above downward and inward and offer *no obstacle to the upward dislocation* of the outer end of the clavicle. This fact explains why this is the common form of dislocation in this joint. The capsule and ligaments of the joint proper are lax and weak so that effusion into the joint is soon visible. It is the *strong coracoclavicular ligament* (coronoid and trapezoid) upon which the strength of the connection between clavicle and scapula depends.

The *upward dislocation* of the outer end of the clavicle may be complete or partial and in the former case the coracoclavicular as well as the acromioclavicular ligaments are torn, in the latter case the former may be torn or merely stretched. In complete dislocation the outer end of the clavicle rides up above the acromion and may be *displaced outward* over the latter. The *cause* is usually a blow upon the point of the shoulder, probably associated with a vigorous contraction of the trapezius, whereby the clavicle is prevented from becoming depressed with the acromion. The rarity of *downward or subacromial dislocation* of the outer end of the clavicle is explained by the oblique direction of the joint surfaces. The cause in most cases was direct violence applied to the outer end of the clavicle.

Whereas *reduction* is commonly easy in both forms, *retention* is difficult, as there is nothing in the shape of the bones to hold them together and the ligaments are torn. In the common upward form upward pressure of the shoulder through the arm and downward pressure on the outer end of the clavicle are accomplished by various retentive dressings but the necessary continuous retention is very difficult. As in dislocation of the sternoclavicular joint the injection of irritants, like 50 per cent. alcohol, to stimulate periarticular connective tissue formation which afterwards contracts and helps to hold the bones together, I have found useful, especially in the incomplete forms. Some patients are seriously *disabled* by this accident, others but little.

In this connection it may be noticed that the *movements* of this joint allow the glenoid cavity to *maintain or alter* its *relative position* in the movements of the shoulder around the sternoclavicular joint as a center. Thus in raising the arm, forward or laterally, the extent of this movement is much increased by the elevation of the glenoid cavity, the scapula moving on an antero-posterior axis through this joint. Again as the shoulder moves forward for a blow or shove or in a fall upon the hand the glenoid cavity is turned forward, so that it may be as nearly as possible at right angles to the long axis of the humerus which it can thus best support. In this way a strong forward "blow from the shoulder" is possible. Otherwise the strain comes upon the capsule of the shoulder and tends to dislocate it. This forward position of the glenoid cavity is due to a movement of the scapula on a vertical axis passing through this joint. Impairment of this joint by accident or disease may therefore cause a limitation in certain movements of the upper limb or an insecurity of the shoulder joint.

**Subclavicular Soft Parts.**—The *interspace* between the *sternal and clavicular portions* of the *pectoralis major* can often be distinguished on the surface just below the clavicle. The sternal portion is often removed in whole or in part in the operation for carcinoma of the breast. The clavicular portion is the more superficial of the two. The *pectoral fascia* is firmly connected with the *pectoralis major*. We may usually be sure that we have divided the *pectoralis major* when we reach a cellular layer, though Heath describes a cellular interval which sometimes lies between two planes of its muscle fibers and may be mistaken for the space beneath it. On removal of the *pectoralis major* we expose the *pectoralis minor* from whose upper border a strong fascia, the *clavipectoral fascia*, extends up to and is continuous with the sheath of the *subclavius* muscle and thence is connected with the clavicle and coracoid process. It is continuous with the sheath of the axillary vessels and the deep cervical fascia. The upper part of this fascia, between the coracoid process and the first rib, is particularly firm and is named the *costocoracoid membrane*. This *fascia* is *pierced by* the *cephalic vein*, the *acromiothoracic artery* and the *anterior thoracic nerve* and *covers* the first portion of the axillary vessels and the *brachial plexus*. The *clavipectoral fascia* *splits to ensheathe the pectoralis minor* and unites below it into a single triangular sheet which extends laterally to the sheath of the *coracobrachialis* and inferiorly to the floor of the axilla, the hollow of which it serves to preserve, hence the name "*suspensory ligament of the axilla*."

The *axillary vein* lies below and internal to the artery which it overlaps, owing to its greater size. Hence when the *axillary artery* is *tied in* its first portion the *aneurism needle* is passed from the *vein side*, or below, to avoid injury to the vein. The *axillary artery* is *crossed in front by the cephalic vein* in its passage to reach the *axillary vein*, but it is separated from this vein by the *clavipectoral fascia*. A part of or the entire *cephalic vein* occasionally crosses in front of the clavicle to join the *external jugular vein*. One of the cords of the *brachial plexus* lies in contact with and on the same plane as the artery and may be and has been mistaken for it in ligation of the artery. These main vessels and nerves are surrounded by more or less *areolar and fatty tissue* containing *lymphatic vessels and nodes* which may be involved secondarily to those of the axilla with which they are continuous. They communicate with the *supraclavicular nodes* above. Along this areolar tissue deep infection and abscess may extend from the neck to the axilla and vice versa.

### The Posterior or Scapular Region.

The *skin* covering this region is firm and there is but little *subcutaneous tissue*. The thick *deep fascia*, by its attachment to bone around the origin of the supra- and infra-spinatus and the teres minor muscles which it covers, encloses them in an *osseous-aponeurotic compartment*, open only toward the insertion of the muscle on the great tuberosity of the humerus. Hence in case of abscess under these fasciae or ecchymosis

from fracture of the scapula the pus or blood cannot readily reach the surface, but follows the muscle sheaths to the humeral head and appears under the head of the deltoid. The *firmness* of this fascia is such that it is difficult to decide whether dense tumors growing from it are connected with the fascia or the bone. The *scapula* is *held in place* by the coraco- and acromioclavicular ligaments and by the serratus magnus, rhomboids, trapezius and levator scapulæ muscles. The so-called "winged scapula," or luxation of the scapula, in which the lower part of or the entire vertebral border projects backward from the chest wall is due to *paralysis* of the lower part or the whole of the *serratus magnus muscle*, which is supplied by the long thoracic nerve.

**Fracture of the body of the scapula** is comparatively rare, owing to the mobility of the bone, its thick muscular covering, the elasticity of the ribs beneath and the soft muscular pad of the subscapularis and serratus magnus between it and the chest wall. In case of fracture the *fragments* are *splinted* by the muscles attached on both sides of it, which prevent much displacement. The *acromion* is more exposed to injury and fracture than other parts of the bone. Some consider many cases of supposed fracture of the acromion as examples of *epiphyseal separation* from the spine, which may occur before the twentieth year, when the epiphyseal union ossifies. But clinically most cases are found to be nearer the end of the acromion, *i. e.*, just in front of the acromioclavicular joint. The dense fibrous tissue, which covers this process and is derived from the two muscles attached to it (deltoid and trapezius), and its dense periosteum help to explain why much *displacement* is *uncommon* and why many fractures are subperiosteal and crepitus is wanting. When the fracture is in front of the acromioclavicular joint the deltoid may pull the fragment slightly downward, but there can be no displacement of the scapula and arm. When the fracture is behind the joint the scapula may still be connected by the coracoclavicular ligaments to the clavicle and there can be but little if any displacement of the arm. Bony union is said to be the exception. It should be remembered that in some cases the union of the acromion and spine does not ossify, so that the presence of motion and a fibrous union between these two parts does not necessarily imply fracture or an epiphyseal separation.

**Fracture of the coracoid process** may occasionally occur as a result of violence or muscular action. Usually it is only one of several fractures resulting from severe violence. In some cases the *line of fracture*, being near the base of the process in the line of the epiphyseal cartilage, which ossifies during the fifteenth year, has suggested that the case was one of epiphyseal separation. Although three powerful muscles are attached to the coracoid process *displacement* is usually *slight* owing to the attachment of the coracoclavicular ligaments which are seldom torn.

The rare fracture of the *surgical neck of the scapula* involves the separation of the coracoid process and the glenoid fossa, together with the triceps attachment, from the rest of the bone. The arm is *displaced*

downward as in a subglenoid dislocation, but the coracoclavicular, coracoacromial and spinoglenoid ligaments are usually untorn and limit the displacement. It is easily distinguished from dislocation of the humerus by crepitus, the ease of reduction and the equal ease of recurrence of the displacement.

Tumors of various kinds, especially osteoma, enchondroma and sarcoma, grow from the scapula and require partial or complete excision. In **partial excision** those parts which are of special importance for the function of the arm—*i. e.*, the glenoid fossa, coracoid and acromion processes, should be preserved if possible. The **entire bone** is **removed** with or without the arm in **sarcoma**. In malignant tumors of the upper end of the humerus and some sarcomas of the axilla the upper extremity, scapula and outer two thirds of the clavicle are removed (**interscapulothoracic amputation** of the arm), after first ligating the subclavian artery. The latter renders the operation bloodless except for the posterior scapular artery along the vertebral border and the suprascapular artery in the supra- and infraspinatus fossæ, these arteries being branches of the first portion of the subclavian. In **complete excision** of the scapula (without ligature of the subclavian) the **subscapular artery**, which runs along the lower border of the subscapularis muscle and gives off the large **dorsalis scapulae** branch crossing the axillary border onto the infraspinatus fossa, must also be taken into account. This branch of the axillary artery *anastomoses* with the posterior scapular and suprascapular branches of the subclavian and is an **important factor** in the **collateral circulation** after ligature of the third portion of the subclavian or the first portion of the axillary artery. The *anastomoses on the acromion* between the suprascapular branch of the subclavian and the acromiothoracic and **circumflex** branches of the axillary assist in this anastomosis. For **resection** of the scapula a horizontal *incision* along the spine and a vertical one along the vertebral border (Ollier's) are very serviceable.

The **suprascapular nerve** is a branch of the fifth cervical and receives a branch from the third and fourth cervical nerves, from which is derived the **phrenic nerve**. The latter also communicates with the **nerve to the subclavius** and these two connections explain the **reflex relations** between the diaphragm or liver and the shoulder, *i. e.*, hiccup from inflammation of the shoulder and pain in the right shoulder in perihepatitis, etc.

### The External or Deltoid Region.

This is equal in extent to that of the **deltoid muscle** which *covers* the upper end of the humerus and the muscles inserted into it, the shoulder joint, the coracoid process and its muscles and the coracoacromial ligament. The **subcutaneous fatty layer** over the deltoid is often well developed and is a favorite situation for **lipoma**. The **deep fascia** ensheathes the deltoid and is closely bound to it. In subglenoid or subcoracoid **dislocation** of the shoulder the head of the humerus no longer bolsters out the **deltoid**, so that the latter is **flattened** and hangs

straight down from the acromion process, which is thereby rendered more prominent and angular. Moreover the attachments of the deltoid being more widely separated than normal the muscle is *put on the stretch* which still further flattens the region and causes a notch or fold at the insertion of the muscle. To *relax the deltoid* the dislocated arm is usually held in the abducted position. If this position is exaggerated, so that the deltoid is very lax, the fingers may be thrust beneath the acromion into the gap left by the dislocated head of the humerus and in thin subjects the glenoid cavity may even be felt.

The *deltoid region* may be *flattened* and a depression be felt beneath the acromion in certain cases where the head sinks away from its socket owing to *paralysis and atrophy of the muscle*, which is supplied by the *circumflex nerve*. (Fig. 40.) This nerve winds around the *surgical neck* of the humerus a little above the posterior circumflex artery, which is two inches below the acromion. This nerve may be *torn, bruised or stretched* in dislocations of the shoulder, in violent attempts at their reduction and in fractures of the surgical neck of the humerus, and it may very rarely be bruised in contusion of the shoulder. As it also supplies the shoulder joint an inflammation of the latter extending along the nerve may cause a neuritis and lead to paralysis of the muscle (Erb). This nerve also gives off a *cutaneous branch* which, winding around the posterior border of the muscle, supplies the skin over its *lower third* (and below it). Thus, according to Anger, we may test the sensibility of this cutaneous branch after dislocations of the shoulder and thereupon base our prognosis as to the future condition of the muscle, for it is not infrequently paralyzed temporarily or permanently.

The deltoid is *not the only abductor* of the arm, being assisted by the supraspinatus, but in paralysis of the deltoid the power of abduction is slight. In *excision* of the shoulder joint the nearer the *incision* is made to the *anterior border* of the deltoid the less of the muscle will be paralyzed by cutting its nerve supply and the smaller will be the branches of the posterior circumflex artery to be divided.

*Beneath the deltoid*, in the layer of loose connective tissue which facilitates the movements of the underlying head of the humerus, is the *subdeltoid or subacromial bursa*, which still further facilitates these movements. As its name implies this bursa also extends beneath the acromion process and this portion is sometimes partly separated from the subdeltoid portion by a constriction. *Beneath the bursa* are the great tuberosity of the humerus and the supraspinatus tendon, but there is *no communication with the joint* unless in dislocation when the supraspinatus tendon is ruptured. This bursa may *hold* about an ounce when distended with fluid, as it sometimes is, causing an undue *prominence* of the deltoid. In case of *abscess* of this bursa the pus may reach the surface at either edge of the muscle, usually the anterior edge, rarely through it. From the point of view of *operative incision* the shoulder joint is *only covered* by the skin, the deltoid and the capsule.

PLATE XV.

FIG. 40.

Posterior region of the shoulder; right side.  
(Joessel.)

The shoulder joint is one that relies for its *strength* largely upon the surrounding muscles, a variety of joint most *liable to dislocation*. The laxity of the capsule and the fact that the articular surfaces are held together by *atmospheric pressure* is shown by the admission of air into the joint, dissected free of its muscular covering. Thereupon the head of the humerus falls away from the glenoid cavity by a considerable interval. The same occurs in cases of old standing paralysis of the deltoid. The acromion and coracoid processes, and the coracoacromial ligament connecting them, form an *arch above the joint*, protecting it but separated from it by the interposed tendon of the supraspinatus and the capsule.

The muscles strengthening the capsule are the subscapularis in front, the supraspinatus above and the infraspinatus and teres minor behind. The tendons of these muscles are *blended with the capsule* in their passage to the small and great tuberosities of the humeral head. They are continuous with one another and are assisted in supporting the joint by the long head of the triceps below and the long head of the biceps above. The latter tendon in its passage through the bicipital groove, which is converted into a canal by the transverse ligament, is accompanied by a *tubular prolongation of the synovial membrane* forming a kind of vaginal sheath for it. There is another constant *gap in the capsule* by which the synovial sac communicates with the *subscapular bursa*, a large pouch between the upper part of the subscapularis and the root of the coracoid process together with the adjoining part of the neck of the scapula. The crescentic gap leading from the joint into the bursa lies just in front of the upper end of the inner margin of the glenoid cavity, between the superior and middle glenohumeral bands. A *bursa* beneath the infraspinatus rarely *communicates* with the joint. In addition the *capsule is unprotected* antero-inferiorly between the subscapularis and the long head of the triceps, where the head can be felt by the hand in the axilla.

The *axillary vessels and nerves* (Fig. 41) lie to the inner side of the joint, separated from it by the subscapularis tendon. In *joint disease* with effusion the shoulder appears full and rounded by reason of the distended capsule, which may cause a separation of the two bones of more than one half inch (Braune). In artificial *distension* the arm becomes slightly *extended and rotated inward*, a position commonly found in joint disease and perhaps due to the rigid contraction of the muscles, of which the latissimus dorsi may have a slight advantage and be responsible for the extension and inward rotation. Special prominences occur in the bicipital and subscapular diverticula. Thus a *swelling* often appears at an early stage in the *groove* between the deltoid and great pectoral muscles. This swelling is sometimes bilobed on account of the unyielding biceps tendon. *Fluctuation* can best be *felt* through the axilla, at the uncovered part of the capsule below the subscapularis. If suppuration occurs the *pus usually escapes* through one of the diverticula, most often the one around the biceps tendon. In the latter case it may extend some distance along the bicipital groove.

If it escapes through the subscapular bursa it is apt to spread between the muscle and the scapula and point at the lower and dorsal part of the axilla. Although the shoulder joint is liable to all forms of *joint disease* the latter are not particularly common here. As the result of disease the various forms of *ankylosis* occur and in such cases Tillaux has suggested division of the clavicle and the formation of a false joint to afford freer movement.

The *long tendon of the biceps* strengthens the upper part of the joint, keeps the humerus against the glenoid cavity, and prevents it from being pulled down when the arm is abducted. It is rarely ruptured and seldom displaced from its groove unless one of the tuberosities is torn away, as occasionally occurs in dislocation of the shoulder. The *inner margin of the glenoid cavity* is the stronger and more prominent, especially below, a fact which indicates an attempt to fortify a weak part of the joint where the head most often leaves the socket in dislocation.

When the arm hangs at the side the glenoid cavity looks outward and forward, nearly midway between the sagittal and frontal planes of the body, and at least two thirds of the head of the humerus are not in contact with it. The entire head is to the outer side of the coracoid process in this position. The glenoid fossa is less than half as large as the articular portion of the head of the humerus on horizontal section and about two thirds as large on vertical section. Thus a considerable portion of the head of the humerus is always in contact with the capsule and in abduction of the arm to 90° the head of the bone presses against and puts on the stretch the lower unprotected part of the capsule, between the subscapularis and triceps tendons. It is in this position, with or without outward rotation, that dislocation of the shoulder is most likely to occur.

In *abduction* of the arm to a right angle the great tuberosity abuts against the upper edge of the glenoid cavity and the upper end of the outer aspect of the humerus against the coracoacromial arch. *Further abduction* is due to the rotation of the scapula, but if the latter is kept from rotating by being held mechanically or by a muscular spasm (*serratus magnus*) and if the motion of abduction is continued a *new center of motion* is formed at the point of contact of the humerus with the coracoacromial arch and the head is forced down against the lower and inner tense part of the capsule, rupturing it. Such is the common *mechanism of dislocation* in cases due to indirect or to muscular violence.

The *infrequency* of the injury in the *first two decades* of life is interesting in connection with Kronlein's theory that in this period fracture of the clavicle is the equivalent of dislocation of the shoulder by direct violence, and dislocation of the elbow the equivalent of dislocation of the shoulder by indirect violence.

**Dislocations of the shoulder** are as numerous as all other dislocations combined, perhaps more so. This *frequency* is fully explained by (1) the structure of the joint (the shallowness of the glenoid fossa,

the large size of the humeral head, the freedom of motion, the long leverage of the arm, the laxity of the capsule and its dependence upon the muscles for its strength); and (2) the exposure of the shoulder to indirect and direct violence. Dislocations of the shoulder are classified, according to the displacement of the humeral head, into (1) anterior or subcoracoid, the common form, (2) downward or subglenoid, not common, (3) backward or subacromial, rare, and (4) upward or supraglenoid, very rare. Only the first two forms demand our consideration.

In **subcoracoid dislocations** the *head* of the humerus *escaping* through the rent in the antero-inferior part of the capsule is **displaced primarily** downward and somewhat forward. Indeed some downward displacement is necessary to allow the head to get beneath the coracoid. But the further downward displacement is resisted by the untorn part of the capsule (outer and anterior parts) whose attachment to the anatomical neck serves as a *new center of motion*, so that when the elbow is lowered after abduction has ceased, the head rises along the inner side of the joint. This **secondary displacement** to a final position, approximately beneath the coracoid (subcoracoid), is also *partly effected* by the contraction of such *muscles* as the pectoralis major, latissimus dorsi and deltoid. The *extent* of this secondary inward *displacement* is *determined* largely by the resistance of the untorn portion of the capsule, the continuance of the dislocating violence, and the degree of contraction of the adductor muscles. Thus the head may be displaced internal to the coracoid process, giving rise to the subvariety "**intracoracoid.**"

In the **subcoracoid form** the *head* of the bone *lies* behind the coracobrachialis and the short head of the biceps and against the edge of the glenoid fossa or the side of the neck of the scapula just internal to it. In the **intracoracoidal variety** it *lies* farther back on the neck and against the serratus magnus, having passed behind the muscles arising from the coracoid process. The head is thus internal, anterior and a little inferior to its normal position. The anatomical neck may rest on the anterior lip of the glenoid cavity.

The **subscapularis muscle** is sometimes pressed inward and separated from the scapula by the interposed humeral head, but in many cases it is torn from its lower border upward to a greater or less extent. Thus the subscapularis may intervene in whole or in part between the coracoid process and the head, or the latter, escaping in front of the muscle, may lie close against the beak of the coracoid, behind the coracobrachialis and short head of the biceps. The *attachment* to the humerus of the *supraspinatus* is probably often torn, that of the infraspinatus less often, or, in place of this rupture of the tendon, the **great tuberosity** may be *torn off*. This latter accident is of importance because it *opens the way for the long biceps tendon* to escape from its groove, slip over the head and become engaged between the head and the glenoid cavity, where it may offer a serious obstacle to reduction. The *rupture* or *avulsion* of the *supra-* and *infraspinatus tendons*, and

their consequent retraction under the acromion, may impair the subsequent motion of the joint by their loss of control over the humerus. They may become interposed between the head and its socket, so as to oppose reduction, or they may open up the subdeltoid bursa and favor the recurrence of dislocation by lengthening and weakening the capsule. The *axillary vessels and nerves* are pressed inward and sometimes ruptured.

In the **subglenoid variety** the *head* usually *rests* against the flattened upper end of the axillary border of the scapula on the inner side of the triceps tendon, the latter preventing its displacement directly downwards. It thus *lies* below and a little internal and anterior to its normal position. It also lies beneath the subscapularis tendon, which is much stretched or torn. The *rent in the capsule* differs from that in the subcoracoid form in not extending so far upward along the anterior edge of the glenoid cavity. The resistance of this untorn anterior part of the capsule seems to be what prevents the head from reaching the subcoracoid position, although in some cases this dislocation may be transformed into a subcoracoid by movements of the arm or even by muscular action. The *supraspinatus* and often the *infraspinatus* are *torn* from their attachments, or the *tuberosity is avulsed* from the humerus. The *cause* of the subglenoid form has almost always been a forcible elevation of the arm.

The **symptoms** in both forms are mainly *due* to the absence of the head from its normal position, the presence of the head in an abnormal position and the consequent altered position or action of the muscles. The *absence of the head* from its socket accounts largely for the flattening of the deltoid region and, in the subcoracoid form, the *empty glenoid socket* can be *felt* through the axilla. In the subglenoid form we can *feel the head* through the axilla, lying below the glenoid fossa  $\frac{1}{2}$ -1 inch below the coracoid process, while in the subcoracoid form it forms a hard prominence of the anterior axillary wall, just below the coracoid process, and causes a fullness of the outer part of the infraclavicular fossa. The *axis of the arm* prolonged upward passes below or internal to the glenoid cavity. The *deltoid is stretched* by the increased separation of its attachments, and this not only increases the *flattening* of the deltoid region and the prominence of the acromion but causes the arm to be *abducted*, which is more marked in the subglenoid variety as the deltoid is more stretched.

As the head is displaced somewhat downward in both forms, *measurement* from the angle of the acromion to the external condyle of the humerus should show *lengthening* as compared with the opposite limb. But owing to the relative position of these two points of measurement in a plane external to that of the glenoid cavity, abduction causes a measured shortening in the normal arm and much more so in the dislocated arm, when the head is displaced more or less inward. Hence the measured *lengthening will depend on the degree of abduction* and may be altogether wanting or replaced by shortening, though seldom so in the subglenoid form, in spite of its greater abduction, on account

of its greater lengthening. The elbow can not be made to touch the thorax for, on account of the rotundity of the thorax, both ends of the straight humerus can not touch it at the same time, and in a dislocation of the shoulder the head of the bone is practically touching the thorax. The *diagnosis* between subcoracoid and subglenoid dislocations can usually be readily made from the differences noted in the symptoms given above.

**Reduction.**—The *obstacles* to this may be the tension of the un torn portion of the capsule, opposing the movement of the head toward the socket, the approximation of the sides of the rent in the capsule, the interposition of portions of the capsule or of the biceps tendon, the contraction and rigidity of the muscles, the edge of the glenoid cavity and, rarely, the interposition of the subscapularis tendon.

The most frequent obstacles are the opposition of the anterior part of the capsule and the contraction of the muscles and these, as well as most other obstacles, may be avoided by *abduction and outward rotation* of the arm. *Traction* in this position, with or without *direct pressure* on the head toward the glenoid cavity, is successful in the great majority of cases. Success in methods employing traction is also largely dependent upon the efficient *fixation of the scapula* by the surgeon, his assistant, bandages or apparatus. Stimson<sup>1</sup> has lately successfully employed a modification of this method by exerting continued traction by a weight on the abducted arm, the latter passing through a hole in a canvas cot. The continued traction of the weight tiring out the muscular contraction, reduction occurs painlessly and spontaneously within six minutes. *Traction upward*, though formerly employed, is *objectionable* on account of the risk of increasing the laceration of the capsule and of injuring the axillary vessels by stretching them around the head of the humerus. Although this method is theoretically suggested by the position of the head in the subglenoid variety yet on account of the risks mentioned trial should first be made of direct reposition by pressure on the head, or this combined with traction in the abducted position.

In the methods of **reduction by manipulation**, *rotation inward* has long been employed to turn the head of the bone into the socket opposite to which it had been brought by traction. Inward rotation constitutes the *last step* in the pure manipulative method now most in use, that of Kocher. In Kocher's method the flexed elbow is pressed against the side (*adduction*) and *rotated outward* until the forearm points directly outward; the arm, rotated outward, is then *carried forward* and *slightly inward*, and *rotated inward*, carrying the hand over to the opposite shoulder. Reduction occurs in the final rotation inward or in the movement forward and inward. Farabeuf thus explains the *mechanism of the manipulations*. The un torn *posterior portion of the capsule* is the efficient agent. This is tightened by the adduction, so as to prevent the posterior surface of the humerus from moving inward or forward when the arm is rotated outward. Hence the attachment of this part of the capsule serves as the fixed point about which the head

<sup>1</sup> Fractures and Dislocations, third ed., p. 565.

rolls or winds outward in outward rotation. In the forward movement, with slight adduction, the head, turning upon the same fixed point, is thrown backward and further outward toward the socket, so that the final inward rotation, unwinding the capsule, leaves the head in place. This method is also applicable to old cases but there is some danger of fracture of the humerus in the outward rotation.

**Associated injuries and complications** of dislocation of the shoulder, in addition to those mentioned, may occur either *at the time of dislocation or during reduction* and it is often difficult to say at which time a given complication has occurred. **Fracture of the anatomical or surgical neck** is indicated by the failure of the head, which is out of the socket, to share the movements of the arm. The dislocated and fractured fragment may sometimes be reduced by direct pressure. Failing in this the following plans were formerly tried: (1) Consolidation of the fracture and then reduction; (2) prevention of union and the formation of a false joint; (3) excision. But open incision is preferable and, in fractures of the surgical neck, McBurney has demonstrated the service, in accomplishing reduction, of a stout bent hook introduced into a hole drilled in the upper fragment. Fracture of the neighboring processes or of the shaft have also been observed.

**Injury to the nerves**, except of a slight and transitory nature, are *not common*; they occur most often during reduction and in the subglenoid variety in which the nerves are tightly stretched around the head. The *circumflex nerve* (see also p. 158) suffers most often and has been entirely or partly ruptured, stretched or compressed. The main nerve trunks have also been compressed.

Serious injury to the **blood vessels** are *not common*, and it is often doubtful whether the injury occurred during the dislocation or its reduction. The *axillary vein* alone has been ruptured in four cases, the vein and artery in two, but in the majority the *axillary artery or one of its branches* has been the vessel injured.<sup>1</sup> In some of the latter there was a complete or partial rupture of all of the coats of the artery, while in others the coats were so injured that rupture or the formation of an *aneurism* followed later. The rupture is usually *high up* where the head pressed inward upon the vessel and in some cases it appeared to be due to the tearing off of a branch, the subscapular or circumflex which run almost directly outward where they are fixed to the tissues among which they branch. Again the latter branches have been torn across at or near their origin, in which case the radial pulse would persist. In *old dislocations* the vessels, especially the outermost one, the artery, becoming adherent to the bone, are *more likely to be ruptured in reduction* for the strain comes on a shorter segment of the vessel, *i. e.*, the segment above the adhesion to the bone. If the vessel is atheromatous the danger is still greater.

**Fracture of the anatomical neck** without an additional line of fracture through the tuberosities is a *rare* and obscure form of injury and occurs most often in connection with dislocation of the shoulder.

<sup>1</sup>Stimson, Fractures and Dislocations, third ed., p. 453.

When the line of fracture passes through the tuberosities the outer part of it is extracapsular, for the outer part of the capsule is attached exactly to the anatomical neck, while internally it is attached some distance below it. From the latter point capsular fibers are reflected upward to the lower margin of the articular head and these fibers blend with the periosteum and usually, but not always, connect the head with the shaft in fracture of the anatomical neck. When the head has a slight vascular connection with the rest of the bone, and probably when it has none, the head does not necessarily necrose but *repair is possible*, being carried on largely by the lower fragment.

The *symptoms* are *obscure*. *Crepitus* may be absent owing to impaction or the ease with which the small upper fragment within the socket shares the movement of the lower fragment. The *lower fragment* may be *displaced* upward and backward by the action of the deltoid and other muscles and in this case there is likely to be slight shortening of the arm. Again the upper end of the lower fragment may be displaced forward and inward by the muscles attached to the bicipital ridges and groove. Up and down movements of the lower fragment may be unusually free and accompanied by pain and possibly by crepitus. If impaction of the fragments occurs, as it may readily do, there may be some flattening of the deltoid.

**Separation of the upper epiphysis** may take place at any time from birth to the time when its conjugal cartilage ossifies, usually by the twentieth year, sometimes as late as the twenty-fifth. It has been observed up to the age of nineteen years. The *upper epiphysis* comprises the head and tuberosities and its *lower border runs* upward and outward along the lower and inner half of the anatomical neck and then transversely under or through the tuberosities to the outer edge, where it lies above part of the insertion of the teres minor. The upper end of the shaft is shaped like a low cone, the height of the cone increasing with age as does the depth of the corresponding cup in the head. The epiphyseal line is so nearly transverse that the complete transverse displacement of the fragments can not often occur, especially as the *periosteum* remains *untorn to some extent*, particularly posteriorly, and where it is torn it is often stripped up from the shaft and torn below the epiphyseal line.

**Displacement.**—The upper fragment is usually abducted, flexed and rotated outward by the muscles attached to the great tuberosity while the shaft is drawn forward and usually inward by the muscles inserted into the bicipital ridges and groove. The anterior edge of the upper end of the shaft may form a distinct forward projection and can usually be plainly felt an inch or more below the acromion. The injury may occasionally cause the *premature ossification* of the conjugal cartilage, and the consequent *arrest of growth* of the arm, for the greater part of the growth in length of the humerus takes place at its upper end. A similar arrest of growth is much more likely to follow an inflammation of the cartilage (*epiphysitis*).

The displacement can usually be *reduced* by direct pressure on the

upper fragment combined with traction on the arm, preferably in the completely abducted position, as the upper fragment is already abducted.

**Fracture of the Surgical Neck.**—The fact that the great majority of fractures of the upper end of the humerus occur between the site of the epiphyseal cartilage and the insertion of the pectoralis and teres major muscles has given the name “surgical neck” to this part of the bone. A fall or blow, or occasionally muscular action, is the *cause*. The upper end is often fixed by the resistance of the capsule, the ligaments and perhaps the muscles, while the elbow is forced in the opposite direction and a blow is received on the outer part of the shoulder so that a “*cross strain*” is produced. Fractures of the lower part of the neck are more apt to be oblique.

The *displacement* is commonly as follows: the upper fragment is abducted and rotated outward by the muscles attached to the great tuberosity while the lower fragment is drawn upward by the deltoid, coracobrachialis and triceps, unless the fracture is transverse or impacted, and its upper end is drawn inward by the muscles attached to the bicipital groove and ridges and by the continuation of the fracturing force. When so displaced the lower fragment may form a projection in the axilla, and be abducted so as to alter the axis of the limb. This displacement is *by no means constant* and in the majority of cases it is too *slight* to be clinically recognizable, especially through the swollen tissues. I have had one case where the sharp upper end of the lower fragment perforated and buttonholed the deltoid, anteriorly, and required an operation to dislodge and replace it.

Failure of the tuberosities to share the rotary movement imparted to the elbow is one of the characteristic *symptoms*. In adopting a *suitable dressing* for these cases the action of the muscles mentioned above as producing the displacement must be opposed, which may be partly effected by using traction by means of weights or the weight of the arm.

**Excision of the Shoulder Joint.**—From an operative point of view the shoulder joint is covered only by the skin and the deltoid muscle and hence is very accessible. It is *most desirable* for the subsequent function of the arm to *preserve the function of the deltoid* by sparing its nerve (the circumflex) which reaches it from behind, hence the *incision* should be *at or near its anterior border*. With this object in view the *incision* begins at the edge of the clavicle, above the coracoid process, and passes down along the anterior margin of the deltoid. The pectoralis major and cephalic vein are retracted internally, the deltoid externally, and the latter may be detached for a distance from the clavicle if more room is required. The acromial branch of the acromiothoracic artery and the coracoacromial ligament are divided. The *capsule* is *opened* along the long biceps tendon and, rotating the bone first inward and then outward, the great and then the lesser tuberosity is cleared of muscular attachments by vertical incisions close to the bone, the biceps tendon being drawn aside. The head can then be thrust up through the slit in the capsule and the neck cleared and divided.

PLATE XVI.

FIG. 41.

Horizontal section through the middle of the glenoid cavity; the arm being adducted, showing the axilla on transverse section. Right side, upper segment of section. (Testut.)

A continuation of the above incision for excision affords one of the best methods (*racket method*) of amputation or disarticulation at the shoulder joint and it allows an excision to be followed by an amputation if the case demands it. The vertical incision is carried down to the level of the axillary fold and then curved outward through the lower part of the deltoid and around the posterior and inner part of the arm and then upward under the anterior axillary fold to end in the vertical incision. In the vertical incision the cephalic vein and branches of the acromiothoracic artery are ligated. After division of the lower part of the deltoid this muscle, with the trunk of the posterior circumflex artery and the circumflex nerve, can be readily raised from the bone by blunt dissection exposing the head, around which the capsule is divided. Then the muscular tissues on the inner side, with the vessels and nerves they contain, are divided after separating them from the bone from above downward to the level of the skin incision. In this step the *main vessels* may be controlled by an assistant compressing them in the inner flap between the thumb and fingers of both hands, or they may be previously ligated through the skin incision. In freeing the insertions of the teres muscles we must keep close to the bone to avoid the circumflex nerve, which passes back between them to supply the deltoid, the chief muscle of the stump.

### The Axilla.

This *pyramidal space* between the chest and the arm may be regarded surgically as a *passageway* between the neck and the upper extremity by which tumors or abscesses may extend from the one to the other region.

**Boundaries.** (Fig. 41.)—**The anterior wall** (Fig. 42) of the axilla is formed by the pectoralis major with its sheath, the pectoral fascia, and the pectoralis minor with its sheath, the *clavipectoral fascia*. From the outer border of the pectoralis minor, where the two layers of its sheath reunite, this clavipectoral fascia extends across in front of the axilla as a triangular sheet to become continuous with the sheath of the coracobrachialis. The lower border or base of this fascia is connected with the axillary fascia and helps to hold up the latter and preserve the hollow of the arm pit.

**The posterior axillary wall** (Fig. 43) is formed by the subscapularis, latissimus dorsi, and teres major muscles, the *inner wall* by the upper four ribs and spaces, covered by the serratus magnus muscle. The *outer wall*, so narrow as almost to deserve the name angle, is formed by the humerus covered by the subscapularis and biceps tendons and the coracobrachialis. The *apex* corresponds to the first intercostal space at the commencement of the axillary vessels and is occupied by these vessels, the lymphatics and the brachial plexus.

**The base**, represented by the *hollow of the arm pit*, is formed by the skin, subcutaneous tissue and axillary fascia which extend between the anterior and posterior borders and are continuous with similar structures on the chest wall internally and the arm externally. The skin of the

base is thin, sensitive and easily chafed so that it does not bear the pressure of apparatus well. It is richly provided with hairs, sebaceous and sweat glands and these glands or the hair follicles are the starting point of the small *superficial abscesses* often met with here. These tend to open through the skin, being separated from the axilla by the strong **axillary fascia**. The latter is *continuous with* the pectoral and clavipectoral fascia in front, the fascia of the latissimus dorsi behind, the sheath of the axillary vessels and the deep fascia of the arm externally and that of the thorax, covering the serratus magnus internally. It effectually *limits the downward spread* of an axillary abscess or hæmatoma as do the other walls of the axilla the extension in their direction. Hence after filling the axilla, and thereby bulging the anterior wall, thrusting back the scapula and obliterating the hollow of the armpit, an *axillary abscess* or hæmatoma may pass up along the vessels into the supraclavicular fossa and the neck. An *abscess* may occur behind the pectoralis major, between it and the pectoralis minor and clavipectoral fascia. Such an *abscess* would be separated from the axilla by the strong clavipectoral fascia and would point along the lower border of the pectoralis major, or possibly in the sulcus between it and the deltoid.

In *opening an axillary abscess* the *incision* should be made at the *center of the base* or floor of the axilla, midway between the anterior and posterior folds, so as to *avoid* the subscapular vessels along the lower border of the subscapularis and the long thoracic along the lower border of the pectoralis minor. It should be *nearer the thoracic or inner wall* than the outer to *avoid* the axillary vessels in the latter situation, but not so near the inner wall or so deeply plunged internally as to wound, as has been done, the long thoracic nerve, which lies on and supplies the serratus magnus. An occasional branch from the axillary or brachial artery crossing beneath the skin of the axilla to the breast, in place of or accessory to the long thoracic, is sometimes found, especially in female subjects, and might be injured in the above incision.

**The contents of the axilla** comprise the axillary vessels and their branches, together with nerves, lymphatic nodes and vessels, areolar tissue and fat.

**The axillary artery** keeps to the outer angle or wall of the axilla in all positions of the arm, forming a curve convex outward and upward when the arm hangs by the side and a straight line from a little external to the middle of the clavicle to the groove on the inner side of the biceps when the arm is abducted to  $90^{\circ}$  and rotated outward. The **axillary vein** lies internal to and somewhat below the artery. It *overlaps* the artery, especially during expiration and in its upper and lower parts, being more separated from it in the middle portion as it takes less of a curve than the artery. When the arm is abducted the vein is drawn over the artery so as to lie almost entirely in front of it and conceal it. The *outer vena comes* of the brachial artery may often be found passing over the lower part of the axillary artery to join the vein which is formed by the union of the *inner vena comes* and the

## PLATE XVII.

FIG. 42.

Infraclavicular fossa after removal of the fasciae. The pectoralis muscle is separated from the clavicle and turned down. (Zuckerkandl.)

FIG. 48.

Axilla from below after removal of fasciae, connective tissue and lymph-nodes. The pectoralis major is raised up. (Zuckerkandl.)

basilic vein. This union usually occurs near the lower border of the subscapularis but sometimes not until just below the clavicle, a condition unfavorable to operations on the artery as it is crossed by many branches which unite the two veins. A *muscular slip* from the latissimus dorsi to the pectoralis major may be found crossing the inner aspect of the axillary vessels in the lower part of their course. This may be mistaken for the *coracobrachialis muscle*, which is the *guide to the lower part of the axillary artery*. The *latter part* is superficial and *easily ligated*, remembering that the vein lies to its inner side, separated from it by the internal cutaneous and ulnar nerves, while the musculocutaneous nerve is external and the median nerve in front and externally, its inner root crossing in front of the artery. The *incision* is behind the anterior axilla fold, in line with the vessel (see above) which lies at the junction of the anterior and middle thirds of the axilla and is separated from the shoulder joint by the subscapular and its tendon, and from the humerus by the coracobrachialis and the tendons of the biceps. The *axillary vein* shows the respiratory wave and its upper part is *held open* by its adhesion to the costocoracoid membrane. Both of these facts increase the liability of the entrance of air in case of its being wounded. The vein is *more often wounded* than the artery, as it is larger, more superficial and overlies it, but in injuries by traction, as in reduction of a dislocation, the artery is more often injured than the vein. The relative *frequency* of *aneurism* of the axillary artery is *attributable to its nearness to the heart, its abrupt curve, its extensive and frequent movements, and its liability to share in the many lesions of the upper limb*. The *axillary nerves* are seldom torn by traction and not often injured by a wound, the median being involved most frequently, the musculospiral least frequently, owing to their relative depth.

The *axillary lymph nodes* are of great *surgical importance*, especially in view of their involvement in septic infection of the upper extremity and cancerous growths of the breast. They comprise *three or four* fairly distinct *groups*; the *axillary nodes proper* (3-4) form a chain along the vessels and receive the lymphatics of the arm; the *pectoral nodes* (4-5) along the course of the long thoracic artery and the lower border of the pectoralis minor and on the serratus magnus receive the lymphatics from the mamma, the front side of the chest and the abdomen above the umbilicus; the *subscapular nodes* (2) along the subscapular artery receive lymph from the back; the *subclavian or infra-clavicular nodes* (2) just below the clavicle on the costocoracoid membrane between the deltoid and great pectoral muscles, receive lymph from the outer part of the arm and the deltoid region. Of these the *most important* are the first and second groups and especially the latter, in connection with cancer of the breast. As they lie along the inner or *thoracic wall of the axilla* it is this wall that should be *palpated* to determine whether there is lymphatic involvement. In persons at all stout I have found it difficult or impossible to palpate nodes only slightly enlarged. Belonging to this group are one or two

nodes at the level of the third and fourth ribs which are usually the first to be involved in cancer of the breast.

As a free communication exists not only between the nodes of each group but between the different groups, infection of any one may extend to all the others. Hence in removing the axillary nodes in a case of cancer of the breast we remove not the pectoral group only but *all the groups* and the fatty and areolar tissue which contains lymph vessels. As the axillary nodes communicate with the deep cervical and the one or two in the supraclavicular fossa, we should examine these in advanced cases to see how far the infection has spread. Some operators regularly remove any in the subclavian triangle in addition to those in the axilla. The entire *axilla* up to its apex is *well exposed* in *Halsted's operation* in which the sternal portion of the great pectoral is removed, its clavicular portion incised vertically and the pectoralis minor divided. The *nodes when diseased* are often *adherent to the axillary vessels*, especially the *vein*, and their pressure on the latter causes the *edema* of the arm often observed in advanced cases.

Although in inflammatory or other affections of the arm the axillary group of nodes are usually enlarged and painful and often break down into an abscess so as to require removal or incision, yet, in at least three cases of profound sepsis of the arm, ending fatally after a time, I found no swelling or tenderness of these nodes in the axilla. But whether this was due to an imperfection of the glands or to the nature of the infection I am unable to say. At least, having observed a similar condition in the lower extremity in two fatal cases I consider the prognosis bad when the glands of the axilla or groin are not enlarged.

### THE REGION OF THE ARM OR UPPER ARM.

This *extends* from the lower limit of the "shoulder," the insertion of the pectoralis major internally and the deltoid externally, to the upper limit of the region of the elbow, two or three fingers' breadths above the condyles.

**Surface Markings and Landmarks.**—Whereas in women, infants and fat subjects the arm is regularly rounded, in muscular subjects it is flattened on each side and especially prominent in front, owing to the distinctly outlined *biceps muscle*. On either side of the latter is a *groove*, of which the inner is much the more marked and runs from the axilla to the bend of the elbow. It indicates the position of the *basilic vein* and the *brachial artery*, the course of the latter, in the extended and supinated arm, corresponding to a line drawn along the inner border of the biceps, beneath the anterior axillary fold, to the middle of the bend of the elbow. It is *superficial* and can be *felt* throughout its entire length. The *outer shallower groove* extends up to the deltoid insertion and indicates the position of the *cephalic vein*, which above the deltoid insertion runs upward and inward along the internal border of that muscle and then in the groove between it and the pectoralis major. The *deltoid insertion* is easily made out and is an important landmark,

indicating the middle of the humeral shaft and the level of the insertion of the coracobrachialis, of the upper limit of the brachialis anticus, of the entrance of the nutrient artery on the inner surface and of the point where the musculospiral nerve and superior profunda artery reach the outer border of the bone. The *shaft of the humerus* is so well covered by muscles that it can only be felt below the deltoid insertion, from whence the outer border can be traced down into the external supracondylar ridge.

**Superficial Topography.**—The course of the *median nerve* corresponds to that of the artery, lying external to it in the upper third, in front in the middle third and internal in the lower third. The *internal profunda artery* is represented by a line from the inner aspect of the brachial artery at the middle of the shaft to the back part of the internal condyle. The *ulnar nerve*, following the brachial artery on its inner side, diverges from it at the middle of the shaft with the inferior profunda and follows a line from this point to the gap between the olecranon and the internal condyle. It may be felt along the back of the internal supracondylar ridge. The *musculospiral nerve*, with the superior profunda artery, follows a line from just below the posterior fold of the axilla downward, backward and outward to the outer border at the deltoid insertion and thence downward to the front of the external condyle, lying between the brachioradialis and the brachialis anticus in the lower fourth of the arm. The lower end of the outer bicipital groove corresponds to the superficial portion of the *musculocutaneous nerve*. The anastomotica magna is given off about two inches above the bend of the elbow.

The **skin** of the arm is smooth and thin, especially anteriorly and laterally, where it is very free from hairs, so that it is here very suitable for skin flaps and for skin grafting. The point of insertion of the deltoid is free from muscular movement so that the overlying skin is very suitable for vaccination, as it was formerly for the application of a seton. The skin is so *loosely attached* by the subcutaneous tissues to the deep fascia that in circular amputation it can be sufficiently drawn up by the traction of the hand and requires no separate dissection to form a flap. If it requires any separation with the knife it is only along the lines of the intermuscular septa. It is more loosely attached on the inner than on the outer aspect of the arm (*i. e.*, over the deltoid). The skin is stripped up equally readily in contused and lacerated wounds.

The **deep fascia** (*brachial aponeurosis*) completely invests the underlying muscles to which it is loosely attached. It is *continuous* with that covering the elbow region below and with the fascia of the deltoid, the axilla and its anterior and posterior walls above. It is thin in front, where it covers the biceps, thicker behind. At the sides it is connected by the internal and external intermuscular septa with the internal and external borders of the bone. The *external intermuscular septum*, the weaker of the two, extends from the external condyle to the deltoid insertion and is *perforated* by the musculospiral nerve and superior pro-

funda artery about midway between the deltoid insertion and the tip of the external condyle. The *internal intermuscular septum* extends from the internal condyle to the teres major muscle (internal bicipital region) and is *perforated* by the ulnar nerve and the inferior profunda artery about two inches above the internal condyle.

These two septa with the deep fascia divide the arm into *two compartments* of which *the posterior contains* the triceps muscle with the upper part of the musculospiral and the lower brachial portion of the ulnar nerves and their accompanying vessels, *the anterior contains* the rest of the brachial muscles and soft parts. These compartments confine to a certain extent inflammatory or hemorrhagic effusions which however can pass from one to the other by following the structures that pierce them. The *brachial aponeurosis* itself is *pierced* along the internal bicipital groove by the internal cutaneous nerve about the middle and by the basilic vein a little below the middle of the arm; and along the external bicipital groove by the external cutaneous nerve, just above the elbow.

The *brachial artery* may be *ligated* in any part of its course. The *best guide* is the inner border of the biceps which may overlap it in muscular subjects. Its changing relations with the *median nerve* (see above) should be remembered, but these are not always constant, so that this nerve is a poor guide. The number of cross branches between the two *venae comites* sometimes embarrasses the operator. The *ulnar nerve* lies close to the inner side in its upper half and may be mistaken for the median if the incision is too far internal. The *musculospiral nerve* is also behind the upper end of the vessel.

Anomalies occur more often in the brachial than in almost any other artery. The most *important anomaly* from a surgical standpoint is its *high division* (even in the axilla) in which case the smaller branch lies in front, the other behind the median nerve. Hence if an artery is found in front of the nerve we should look for another behind it. Again in the lower part of the arm the artery or one of its branches may deviate internally to pass to the inner side of the supracondylar process with the median nerve. *Behind the artery* lies the coracobrachialis for a short distance, lower down the brachialis anticus. The *artery lies internal* to the humerus in its upper half or more, in front of it below; so that it *may be compressed* against the bone by pressure outward and slightly backward above, and directly backward below. Unless this pressure is applied carefully by the fingers the median nerve can hardly avoid pressure, the result of which is the pain often complained of after the application of a tourniquet.

The *lymph vessels* are largely superficial. Most of these 15–18 accompany the basilic vein where they can readily be seen as a band of red striae in lymphangitis. A lymph vessel usually accompanies the cephalic vein.

The *musculospiral nerve* in its passage along the musculospiral groove is in close contact with the bone and hence *may be injured* in contusions and wounds and especially in fractures of the humeral shaft. It

may also escape injury at the time of fracture to be subsequently involved and *compressed in the callus*. In many cases an operation has become necessary to free it from the canal of callus or bone in which it is compressed. It has also been paralyzed by the pressure of the head resting upon the supinated and abducted arm in sleep. In its upper part, on the inner aspect of the arm, it is the nerve which most often suffers from *crutch paralysis*, the ulnar coming next in frequency. In all such cases, besides pain along the course and in the branches of the nerve, the symptoms of paralysis resemble those in lead-palsy, which also affects this nerve. The extensors of the wrist and fingers are paralyzed and "*wrist-drop*" is produced, indicating the inability of the extensors to extend the wrist.

The *nerve* is most conveniently *exposed* after it has pierced the intermuscular septum *by an incision*, following the anterior border of the brachioradialis, whose center is opposite the point of perforation of the septum or midway between the deltoid insertion and the external condyle. It is sought for as it enters the gap between the brachioradialis and the brachialis anticus. If it is to be exposed on account of injury in the musculospiral groove the incision is carried along the posterior margin of the deltoid insertion.

**Fracture of the shaft of the humerus**, or that part between the insertion of the pectoralis major and the upper part of the supracondylar ridges, is most often due to direct violence, sometimes to indirect violence. It is more often broken by *muscular action*, such as throwing a stone or the trial of strength known as "*wrist turning*," than any other bone in the body. The *displacement* is usually inconsiderable and depends largely upon the fracturing force. Secondarily the muscles attached to the two fragments may have some effect upon their relative position. Thus the lower fragment is often drawn up by the biceps and triceps muscles, but the weight of the arm resists any considerable shortening. Theoretically in fractures above or below the deltoid insertion the lower or upper fragments respectively would be drawn outward by the action of the deltoid but practically the displacement is usually independent of this action.

**Delayed union and non-union** are of much more frequent occurrence in the humerus than in any other bone. Among the *causes* that lead to this may be mentioned, (1) the *interposition* between the fragments of *muscular tissue* with which the bone is almost completely surrounded, the two fragments being driven into muscular masses on opposite sides of the bone; (2) the *defective immobilization* of the fragments due largely to the imperfect fixation of the joints above and below. According to Hamilton the flexed elbow soon becomes stiff by reason of muscular rigidity so that the movement of the forearm in flexion and extension of the elbow imparts a horizontal or lateral movement to the upper end of the lower fragment. But this alone cannot account for the condition for it would cause a greater movement of the fragments of fractures high up in the shaft and non-union is more common in the middle third.

**Amputation of the Arm.**—*In the lower half* the circular amputation is best. The division and retraction of the skin has been already referred to. As only the biceps has no attachment to the bone it retracts most and requires separate division a thumb's breadth below where the other muscles are divided, at the edge of the retracted skin. After division of the muscles and continued retraction of the soft parts the fleshy cone may again be divided at its base, at the level of the fully retracted skin.

*Above the middle* of the arm the biceps, long head of the triceps, deltoid and coracobrachialis may all retract considerably and unequally, hence amputation by long anterior and shorter (one half of anterior) posterior flaps has some advantages. The brachial artery should be in the posterior flap. The *principal arteries cut* are the brachial (with the median nerve), the superior profunda on the postero-external aspect (with the musculospiral nerve) and in the lower half of the arm the inferior profunda on the inner aspect (with the ulnar nerve). (Fig. 44.) In the flap method all the principal arteries divided are in the posterior flap.

To reach the humerus for removal of sequestra, etc., incision along the outer border is preferable, for the musculospiral nerve is the only structure which need be avoided.

### THE REGION OF THE ELBOW.

The *limits* of this region may be arbitrarily assigned as two or three fingers' breadths above and below the "fold of the elbow." The elbow is flattened from before backward.

**Surface Markings and Landmarks.** (Fig. 45.)—*In front* are visible *three muscular elevations*, one on the outer side corresponding to the brachioradialis and the extensor group, one on the inner side corresponding to the pronator radii teres and the flexor group, and one in the center corresponding to the biceps. The two lateral elevations converge and meet below, enclosing between them a depression, *the cubital fossa*, into which the biceps tendon is felt to sink toward its insertion. From this fossa *two grooves* forming a V are continued upward along the two sides of the bicepst endon, to become continuous with the bicipital grooves of the arm. The details are distinct only in thin or muscular subjects. The *biceps tendon* is plainly felt, especially along its outer border, the inner border being covered by the *bicipital fascia*. The "*fold of the elbow*" is a transverse crease in the skin of the front of the elbow extending transversely, with a slight convexity downward, between the two condyles. Hence it is some little ways, 2–4 cm., *above the joint line*. It is obliterated in extension and not constant in position so that it is not of great service as a landmark. It may be of some use, as employed by Malgaine, to diagnose between an ordinary dislocation of the elbow and a supracondylar fracture of the humerus, the lower end of the humerus projecting below this fold in the former and the lower end of the upper fragment forming a prominence above it in the latter.

# PLATE XVIII.

FIG. 44.

Cross section through the middle of the right arm of a female.  
Upper segment viewed from below. (Tillaux.)

FIG. 45.

Front of right elbow; superficial view. (Joessel.)

The two condyles are plainly felt, the inner and more prominent one even in conditions of extreme swelling. About 2 cm. below the more rounded external condyle the rounded *head of the radius* can be felt, especially on rotating the forearm. In extension of the elbow a marked depression indicates the position of the head of the radius and corresponds to the interval between the brachioradialis and the anconeus muscles. The two humeral *condyles* are in the same transverse line with one another and, when the arm is extended, with the tip of the plainly felt *olecranon process*. When the elbow is flexed the tip of the olecranon comes to lie below the intercondylar line. These relations are of great importance in differentiating dislocation from supracondyloid fracture, for in the latter case they are preserved, in the former they are altered. Furthermore in full extension the point of the olecranon is nearly in the same transverse vertical plane with the two condyles, while in dislocation it is displaced backward. The *olecranon* does not lie midway between the two condyles but nearer the internal condyle, by 12 to 15 mm., so that the groove between the olecranon and the inner condyle is narrower as well as deeper than that between the olecranon and the outer condyle. Neither the coronoid process or the radial tubercle can be distinctly felt in ordinary subjects.

**Topography.**—The joint line of the elbow is only about two thirds (4 cm.) of the width between the condyles and, while it nearly corresponds externally with the lateral limit of the condyle, its inner end is some distance (nearly 2 cm.) external to the internal condyle. This partly accounts for the prominence of the internal condyle. The line of the humeroradial joint is horizontal and can be felt between the head of the radius and the external condyle, that of the humeroulnar joint slopes obliquely downward and inward so that the inner end of the trochlea is 1 cm. below the outer end. The obliquity of the humeroulnar joint makes the axis of the extended forearm to diverge outward at an angle of 6°, accounting for the “carrying function.” It also makes the hand to be carried up toward the face in flexion, unless the forearm is supinated.

The ulnar nerve, lying in the deep and narrow depression between the olecranon and the internal condyle, is exposed to injury by pressure against its hard bed. Pressure on it gives the peculiar numbness and tingling of the ulnar side of the hand, etc., and is known as hitting the “funny bone.” It was wittily remarked that it was so named because it bordered on the humerus. The nerve may lie in front of the internal condyle or slip in front on flexion of the elbow (Quain). It is particularly important to avoid it in excision of the elbow by keeping close to the bone in its neighborhood. In a case of ankylosis of the elbow with much overgrowth of bone, due to a bad fracture, I have found the nerve in a bony canal.

The brachial artery lies in the inner of the two grooves in front of the elbow, just internal to the pearly white biceps tendon, which is an excellent guide to it, and rather more external to the median nerve. It passes under the bicipital fascia where it bifurcates about half an inch

below the center of the bend of the elbow. It may be compressed by forcible flexion of the joint so as to diminish or even stop the radial pulse. Accordingly *aneurisms* here, more frequent in blood-letting days, have been treated by compression, by flexion of the elbow. In the fully extended position the artery is somewhat flattened beneath the bicipital fascia so as to lessen the radial pulse, or even to stop it in the hyper-extension possible with fracture of the olecranon or dislocation of the elbow. It has been ruptured by the forcible straightening of a stiff, bent elbow.

The **median vein** is joined by the deep median vein and *divides into* the median basilic and median cephalic in the depression at the apex of the V (*cubital fossa*). The *median basilic vein* crossing superficial to the biceps tendon and fascia comes to lie in the inner groove where it joins the posterior ulnar vein a little above the internal condyle, forming thereby the basilic vein. Similarly the *median cephalic*, *passing* up in the outer groove, forms the cephalic vein by joining the radial vein about the level of the external condyle.

An M-shaped figure is thus formed by the veins in front of the elbow, but this typical arrangement is by no means constant, occurring only in about 50 per cent. of cases. But in almost all cases a communicating vein crosses the biceps tendon and fascia obliquely, and therefore overlies the brachial artery, and this vein is usually large enough for venesection or intravenous infusion.

The **median basilic vein** or its substitute may *cross* the artery transversely or obliquely or it may run nearly parallel with it, in front of it or to one side. Of all the veins in front of the elbow the median basilic is usually *the largest*, the most prominent, the nearest the surface and the one *least subject to variation*. Hence it was the one most often chosen for venesection in blood-letting days, and now is often chosen for intravenous infusion, in spite of the fact that it is separated from the artery beneath by the *bicipital fascia* only. This membrane, whose density depends upon the muscular development, is an excellent protection to the artery, but on account of the blind method of venesection formerly employed it is not strange that the artery was often wounded, giving rise to aneurism or arteriovenous aneurism, the latter being more common at the elbow than anywhere else. The *median cephalic* is therefore safer, but with open exposure of the vein, as for intravenous infusion, it seems scarcely possible to wound the artery.

Of the *cutaneous nerves* at the elbow the *external cutaneous* passes behind the median cephalic vein, the anterior division of the *internal cutaneous* passes behind or (less frequently) in front of the median basilic. Hence the latter nerve or its branches may be wounded in opening the median basilic vein, an injury that, according to Tillaux, may lead to intense and chronic neuralgia. Small twigs of the external cutaneous nerve may cross in front of the median cephalic and the injury to these branches, or possibly the main trunk behind the vein, and their inclusion in the scar may lead, according to Mr. Hilton, to a reflex contraction of the elbow, due to the contraction of the biceps

and brachialis muscles which are supplied by it. He has cured the condition by resection of the scar which was found to have included some of the nerve filaments.

The *superficial lymphatics* accompanying the veins, lying in front of them, and are most numerous on the antero-internal aspect of the elbow. Situated in front of the intermuscular septum, an inch above the internal condyle, is the *epitrochlear lymph node* (sometimes two nodes), the lowest node in the upper limb. It may become inflamed in any injury or inflammation of the ulnar side of the hand and forearm and the inner two or three fingers, from whence it receives lymph vessels. Around the elbow-joint is an *extensive and free anastomosis* between branches of the superior and inferior profunda and the anastomotica magna, from the brachial above, and branches of the anterior and posterior ulnar, posterior interosseous and radial recurrent from the ulnar, interosseous and radial arteries below. This anastomosis provides a *collateral circulation* in case of ligature of the brachial or in aneurism at the elbow.

The skin about the elbow is thin and fine in front, where it is readily excoriated by tight bandages or poorly applied splints; it is thicker and less sensitive behind. Although the thin skin in front allows the veins to be clearly seen through it, yet in subjects with much subcutaneous fat it may be difficult or impossible to see them. Between the skin and the olecranon is a *subcutaneous bursa*, not infrequently the seat of a *bursitis* with the accumulation of serum or of pus. Occupations involving pressure on the elbow favor bursitis here, of which "miner's elbow" is an example.

The **elbow joint** depends for its strength largely upon the shape and relation of the bones forming it, reinforced by the overlying muscles and the lateral ligaments. Only flexion and extension are permitted; the presence of *lateral motion* shows that the ligaments are torn or stretched as in dislocation or tubercular disease and hence is a *sign of some lesion* of the joint. The *internal lateral* is the strongest and *most important ligament* of the elbow and, as it resists lateral strain as well as limits flexion and extension, it suffers most often from sprains and dislocations. Its attachment to the entire inner border of the great sigmoid cavity of the ulna prevents the wide separation of the fragments in fracture of the olecranon for part of it is attached above and part below the line of fracture. The *anterior and posterior parts* of the capsule are the weakest, especially the posterior portion which presents two pouches, one on either side of the olecranon. As this is also the most superficial part of the joint the *effusion in joint disease* is first noticed as a *fluctuating swelling* here. The line of the *radio-humeral joint* also shows some swelling at an early stage and here, or in the pouches on the sides of the olecranon, especially the external one, the joint may be aspirated or injected. Beneath the brachialis a deep-seated bulging of the thin anterior part of the capsule is also observed in effusion into the joint. Normally the joint surfaces are in contact in all positions, but if the soft parts are divided the radius and humerus

separate by a slight interval when the capsule is incised, readily allowing the knife to enter the joint in exarticulation.

In case of *suppuration* in the joint the *capsule is likely to give way* at its weakest point, *postero-superiorly*. The pus thus comes to lie between the triceps and the humerus, burrows between them and points at either border of the muscle. In other cases it may perforate the thin anterior ligament beneath the brachialis and point near the insertion of the latter.

The *diseased elbow* is usually *held in a position of semiflexion*, a position assumed when the joint is forcibly injected (Braune), for in this position it holds the most fluid. In disease however the position is probably *due to a reflex contraction of the biceps and brachialis muscles*, supplied by the musculocutaneous, which is the principal nerve of the joint. Owing partly to the accurate coaptation of the ulna and humerus *ankylosis* of the elbow after injury, disease or even disuse in a fixed position is *not uncommon*. Sudden forcible straightening of an ankylosed elbow entails some danger of rupture of the brachial artery at the bend of the elbow. If the elbow is ankylosed in a straight or semi-flexed position, the ankylosis should be broken up or the elbow excised, for in this position the arm is not only useless but in the way.

In *excision* of the elbow joint the *three most important muscles* in relation to it, which act on it and therefore *must be preserved*, are the biceps, brachialis and triceps. The insertions of the first two are readily preserved. The ulna may be divided low enough to remove the entire coronoid process without sacrificing the insertion of the brachialis into the tuberosity at its lower end. The usual and best *incision* is a *longitudinal one through the triceps* which is then separated from the ulna on either side of the incision by longitudinal cuts close to the bone (subperiosteally) in order, as far as possible, to leave the triceps insertion in connection with the periosteum of the bone below the point of section. The strong expansion from the outer margin of the triceps tendon should always be saved as it enables the triceps to retain a hold on the forearm. In freeing the parts about the internal condyle great care should be taken to *avoid injury to the ulnar nerve* lying behind it, by making whatever incisions are necessary close to bone and longitudinal. The nerve should not be seen. Another nerve in some danger of injury when the upper end of the radius is being bared is the posterior interosseous as it winds around the radius in the supinator muscle. It is wise to *remove two inches of bone* (including both humerus and forearm bones) to avoid the danger of re-ankylosis.

In connection with excision in young subjects under 17 (when the humeral epiphyseal line ossifies) it may be noted that the *principal growth in length of the humerus occurs at the upper end*.

**Dislocation of the elbow** is more *common* than that of any single joint save the shoulder. It is most common (85 per cent.) *in the first twenty years* of life when, according to Krönlein, it is the equivalent injury of dislocation of the shoulder by indirect violence.

Dislocation of both bones of the forearm backward is the *typical form*, being by far the most common. It is usually due to a fall on the outstretched hand by which the elbow is *hyperextended* and often *abducted*. It is only in hyperextension that the beak of the olecranon presses against the bottom of the olecranon fossa. It then serves as a fulcrum so that by continued hyperextension the ulna is torn as it were from the humerus. The internal lateral ligament is thereby torn, usually at its insertion into the humerus, the external lateral ligament is usually torn or detached from the humerus and the rent extends across the thin anterior ligament. These lateral ligaments oppose hyperextension and lateral motion and are the strongest bonds holding the bones together. Hence when they are torn the violence continuing forces the coronoid process far enough backward to be pushed up behind and above the trochlear surface, opposite to or into the olecranon fossa.

**Associated Injuries.**—The *orbicular ligament* is rarely injured and a partial preservation of the external lateral ligament may affect the attitude of the limb, adducting it, and render reduction difficult. The *brachialis* is stretched, sometimes lacerated and rarely torn across. The *biceps* is rendered tense and occasionally slips around the outer condyle. The *median and ulnar nerves* may be greatly stretched. The *tip of the internal condyle* is often torn off and may be displaced upward with the internal lateral ligament. A common lesion of practical importance is the *stripping up of the periosteum* at the *back of the external condyle*. If the dislocation remains long unreduced new bone is here produced which interferes with the extension of the elbow by impinging on the radius. As *complications* there may be *fracture* of the coronoid process, olecranon, head of the radius (partial or complete) and the shaft or lower extremity of the radius.

**Symptoms and Signs.**—*The crucial signs, on which alone the diagnosis should rest*, are the relative positions of the two condyles, the olecranon and the head of the radius, as determined by palpation. The *olecranon* is *displaced* backward and upward, the backward displacement being more marked in flexion, the upward in extension. The *head of the radius* can be *felt* and perhaps even *seen* under the skin behind the external condyle and to the outer side of the olecranon. In addition the elbow is usually flexed at an angle of about  $135^{\circ}$  but may be extended or even hyperextended, the lower end of the humerus causes a *fullness in front* (below the crease of the elbow), the *forearm appears shortened* in front and broadened above, its *axis* may be deviated to either side, flexion and extension are limited and painful and *lateral motion exists*.

**Reduction** is often accomplished by flexion and traction, using the knee in the bend of the elbow as a fulcrum and to produce traction. In this method the coronoid process has to pass down behind and then below the trochlea and to do this the ulna must be separated from the humerus by more than half an inch, the height of the coronoid process. This can only occur when the laceration of the ligaments and soft parts is extensive or, as often happens, is made so by the process of

reduction. It also requires simultaneous elongation of the muscles of the front and back of the arm. Forceful pronation may facilitate it.

A method more in line with the principle that a dislocated bone should be returned along the route by which it was displaced with the least possible additional rupture of the soft parts, is the method by traction upon the extended or hyperextended forearm; followed by flexion of the elbow or by direct pressure forward on the upper ends of the radius and ulna and backward pressure on the lower end of the humerus.

*As to other forms of dislocation* at the elbow it may be noted (1) that both bones are more often dislocated together than separately for the radius and ulna are connected by powerful ligaments, the radius and humerus are not. (2) That antero-posterior displacements are much more common than lateral ones on account of the lateral width and the antero-posterior narrowness of the joint, the absence of lateral movement and the presence of antero-posterior movement, the feebleness of the antero-posterior ligaments and muscular support and the strength of the lateral ligaments and the support afforded by the lateral muscles. (3) That the rarest dislocation of both bones is forward, for it is resisted by the large strong olecranon process. (4) That if but one bone is dislocated it is most often the radius, for it is less strongly connected with the humerus and more exposed to indirect violence through the hand.

**Dislocation of the radius alone** may occur in the forward, backward or outward direction, usually forward. In luxation of the radius forward the head of the bone arrests flexion of the elbow at or near 90° by impact upon the humerus. It may be due to direct violence from behind, extreme pronation with traction, or to falls upon the pronated or supinated hand while the elbow is hyperextended. The elbow is slightly flexed, almost always pronated and often abducted. Reduction may usually be accomplished by traction combined with supination, adduction and direct pressure upon the head of the radius but it is sometimes resisted or recurrence favored by the interposition of a portion of the capsule or the torn annular ligament between the head of the radius and the humeral condyle.

**Dislocation of the radius by elongation** or the "Subluxation of the radius of young children" is an injury quite common between the ages of one and three, less common up to six, and is due to forcible traction on the extended elbow, possibly combined with adduction as in lifting a child or holding it when it stumbles. *Symptoms.*—The child cries with pain, refuses to use the elbow, which is slightly flexed; the wrist is pronated, and there is tenderness over the head of the radius. Passive motion is free except for supination. The *injury consists in* the escape of the anterior portion of the radial head below the orbicular ligament and is readily reduced by forcible supination with pressure backward on the head of the radius followed by flexion of the elbow. It is sometimes spoken of as sprain of the elbow.

*Luxation of the ulna alone* is usually backward but may rarely be forward or inward. Although all kinds of dislocations of the elbow have been described as *complete* or *incomplete* the differences are often inconsiderable and unimportant. Incomplete forms are more liable to occur in the lateral than in the antero-posterior varieties.

**Fractures of the lower end of the humerus** are more *common* than those of the upper end or the shaft and are *more common in young subjects* than in adults. Various forms occur, rendering a differential diagnosis necessary and often difficult.

**A. Supracondyloid fractures** or fractures above the condyles are due to violence, acting as a rule through the bones of the forearm, pressing the lower end of the humerus (1) backward, by the partly flexed forearm or possibly by hyperextension ("extension fractures"), (2) forward from behind ("flexion fracture") or (3) inward ("adduction fracture"), (1) is oblique from behind downward and forward (the common form); (2) is oblique in the opposite direction and (3) is oblique from above and externally downward and inward. Forms (1) and (2) may be transverse or oblique from side to side. The character and extent of the *displacement* vary with the direction of the fracture.

In the *common form* (1) the *lower fragment* with the bones of the forearm is *displaced* backward and upward by the original violence aided perhaps by the triceps, biceps and brachialis muscles. Hence the sharp lower end of the upper fragment projects forwards and the *deformity resembles a dislocation*, from which it may be distinguished by the relative position of the two condyles, the olecranon and the radial head (see above, p. 175) and by the fact that the displacement is readily reduced and as readily recurs. The *displacements to avoid in the treatment* are overriding and a lateral angular one in the position of adduction (*cubitus varus*), due to the support of the elbow by the sling, which should be only beneath the wrist, and perhaps to muscular action or a primary displacement in an "adduction fracture" (form (3)).

**B. A T-shaped or intercondyloid fracture** may be like the supracondyloid form with the addition of a vertical fracture running through the thin portion of the bone between the condyles into the joint. But as they are commonly due to great violence the bone is often much comminuted and the fractures run in various directions, the *essential fracture* being a *separation of both condyles from each other and from the shaft*. On theoretical grounds the longitudinal ridge of the sigmoid cavity has been thought to act as a wedge in producing the vertical fracture into the joint. The artery or nerves about the joint may be torn or compressed in this or the preceding variety but less frequently than might be expected.

For surgical purposes the terms *epitrochlea* and *epicondyle* are applied to those portions of the internal and external condyles (respectively) which are outside of the joint capsule.

**C. Fracture of the epitrochlea** often *accompanies dislocation* of the elbow, when it is probably due to traction of the forearm flexor

muscles, or it may be *due to direct violence* from behind. The *displacement* may be downward in the direction of the muscles attached to it but the dense periosteal-aponeurotic covering and the attachment of the internal lateral ligament prevent much displacement. The epitrochlea is a *distinct epiphysis* which joins the shaft at about the age of eighteen, and before this age *may be separated* from the shaft instead of fractured.

**D. Fracture of the epicondyle** is *rare* if it ever occurs, and many deny the possibility, owing to its small size.

**E. In fracture of the internal condyle**, usually *due to a fall on the flexed elbow or to forced ad- or abduction of the forearm*, the *line of fracture* extends from the inner border of the epitrochlea, or the ridge above it, downward and outward through the outer part of the trochlea or even beyond it. The ulna is attached to the fragment and *much displacement* of these two is *prevented* by the attachment of the former to the radius, unless this is dislocated as occasionally happens. A *late lateral displacement* in the adducted position (*cubitus varus*) may occur in this as in supracondyloid fractures, from the same cause (see p. 181), and should be guarded against. The relative position of the epitrochlea and the tip of the olecranon is preserved and their displacement with reference to the epicondyle is generally too slight to be recognized.

**F. Fractures of the external condyle** are *more common* than those of the internal condyle and are *especially frequent in the young*. They are *due to a fall on the hand or the inner and back part of the flexed elbow or to forcible adduction of the forearm*. The *line of fracture* runs from the supracondylar ridge above the epicondyle downward into the joint usually to the groove of the trochlea, coinciding in part with the epiphyseal line. In children it is likely that this form of fracture often consists of a separation of the capitellar epiphysis, usually combined with the splitting off of a small piece from the outer side of the diaphysis. As the fragment is attached by ligaments to both the radius and the ulna, the *displacement* is *usually slight*, but there is a tendency to tilting (flexion) and sometimes to a rotation of the fragment. As in fractures of the internal condyle there is independent mobility of the condyle, usually with crepitus, abnormal lateral mobility and pain on transverse pressure and at the point where the fracture crosses the supracondylar ridge. In both forms, even with satisfactory reduction of the displacement, the range of motion may be diminished by callus obstructing the olecranon or coronoid fossa, etc.

**G. Separation of the lower epiphysis** as a whole is rare and improbable, except at an early age, on account of its irregular outline. The portion comprising the united epiphyses of the radial condyle, capitellum and trochlea unite with the shaft in the seventeenth year and that portion including the capitellar and epicondylar nodules is not infrequently separated in the elbow injuries of children (see above). The epitrochlea unites about the eighteenth year. A prominent feature of several of the reported cases has been a *backward displacement* of

the forearm (like a dislocation) but with an easy restoration to place and easy recurrence of displacement.

**H. Fracture of the olecranon** is commonly due to direct violence by a fall upon the elbow and it is uncertain what action if any the triceps muscle may have in producing or assisting in the production of the fracture. The *line of fracture* is most often near the constriction at the middle of the process while the *epiphysis*, which unites with the shaft in the sixteenth year, comprises only the summit of the process.

The *upper fragment* is seldom much separated by the action of the triceps as it is held to the *lower fragment* by the extension of the triceps insertion, the internal lateral ligament and its own aponeurotic attachments, which are usually untorn. In fact whatever separation there may be is rather due to the descent of the lower fragment in flexion of the elbow. The *repair* is as a rule by *fibrous union*.

**I. Fracture of the coronoid process** is very rare except as a complication of backward dislocation of the ulna or of both bones of the forearm. In a recent case of this kind, owing to its tilting forward and interfering with flexion of the elbow I was obliged to remove it. It cannot be caused by the action of the brachialis as the latter is inserted into the ulna at the base of the process rather than into the process itself.

**J. Fracture of the head or neck of the radius** is rare. Fracture of a part of the head is sometimes observed in dislocation of the elbow. I have recently observed such a case where the notch could be felt on rotation of the radius and the fragment was felt in close proximity but could not be replaced, and was removed.

## THE FOREARM.

This region extends from the region of the elbow to two fingers' breadth above the radial and ulnar styloid processes (Joessel). It is conical in form, flattened from before backward, especially in muscular subjects, more rounded in women, children and non-muscular subjects on account of the accumulation of fat in front and behind and the slight development of the lateral muscles. On account of its conical form circular amputation without splitting of the skin flap is not appropriate to the forearm.

**Surface Markings and Landmarks.**—The *ulna* can be felt, along its posterior border, the entire length of the posterior surface of the forearm. In muscular subjects its position is marked by a groove external to which is an elevation, extending from the back of the external condyle down the middle of the posterior surface, formed largely by the extensor communis. Separated from this by a groove is another prominence on the outer aspect of the forearm, formed by the brachioradialis and the two radial extensors. The upper fleshy part of these muscles covers the *radius* so that its upper half can not be felt. But in the lower half of the arm its lateral surface can be felt, though less plainly than the ulna for it is covered by the tendons of the two

radial extensors of the wrist and, about two inches above the radial styloid process, it is crossed by the extensors of the thumb which form a slight ridge directed obliquely downward, outward and forward. On the anterior surface of the supinated arm in thin subjects two slight furrows can be seen, one from the middle of the bend of the elbow to a point just internal to the radial styloid process, the other from the internal condyle to the radial side of the pisiform bone. These two furrows represent respectively the *course of the radial and the lower two thirds of the ulnar arteries*, along which one incises to ligate them. They also represent the anterior borders of the brachioradialis and the flexor carpi ulnaris respectively. The *course of the upper third of the ulnar artery* is represented by a line, slightly convex inward, from the middle of the bend of the elbow to the junction of the middle and upper thirds of the line indicating the course of the rest of the ulnar artery.

The skin of the forearm is thin and movable and the surface veins show through it unless the subcutaneous fat is abundant. It is to be noted that over the middle of the posterior surface, especially in its upper part, there are almost no veins and only very small nerves, and that this is the aspect of the limb most exposed to injury. The fascia, which in the upper half of the forearm is closely attached to the muscles, is free from the tendons in the lower half and attached to the posterior borders of the ulna and radius so as to incompletely divide the forearm into *two compartments* with the aid of the interosseous membrane.

**Arteries.**—The free *anastomoses* between the radial and ulnar arteries is to be remembered in wounds of either vessel. In ligating either vessel by an incision along the lines just given it is to be noted that the *sheath of the radial* is connected with that of the pronator radii teres, in the upper half of the forearm, and the *sheath of the ulnar* with that of the flexor profundus, upon which it lies, so that to freely expose these arteries the sheaths of these two muscles must be divided. Also in ligating the ulnar artery in the lower two thirds of the arm the *ulnar nerve* is almost necessarily *exposed* on its ulnar side, while in ligating the radial artery the *radial nerve* is *not exposed* as it lies further to the radial side and is connected with the sheath of the brachioradialis. Among the *arterial anomalies* of practical interest may be mentioned: (1) the perforation of the deep fascia by the *radial artery* in the middle or lower third of the forearm and its *subcutaneous course* around to the back of the first interosseous space. It can be easily injured in its subcutaneous portion and if the radial pulse is sought in its usual place it is weak, being furnished by the smaller superficialis volæ branch. (2) In case of a *high origin* of the *ulnar artery*, from the axillary or brachial, it usually pierces the fascia and becomes superficial a little above the elbow and thence, passing under or sometimes over the bicipital fascia, its *course* in the upper third of the forearm is *superficial*, covered by the fascia as a rule but sometimes not.

**Skeleton of the Forearm.**—Of the two bones the ulna is the strongest and extends furthest above, the radius below, and the two are most nearly of equal strength about the center of the limb. In all parts the two bones are *nearer the posterior* than the anterior aspect and especially so in the upper part. They are nearest the center of a section of the limb in the lower end of the middle third. On account of the posterior position of the bones, especially the ulna, they are best examined or reached for excision on this aspect; also fractures are most readily compounded posteriorly. The two bones approach one another above and below and are separated in the middle, the separation being widest a little below the middle of the forearm. In *supination* both bones are *parallel*, in *pronation* they are *crossed*. The *interosseous space* is narrowest in pronation, widest midway between pronation and supination, hence the latter position is maintained in most fractures of the forearm. In pronation and supination the *ulna remains stationary*, the radius revolving around it describes half a cone whose apex is above in the center of the radial head and the base below. *Supination is the stronger* of the two movements, thus in using a screw driver, gimlet, or cork screw the main force is applied during supination. In ordinary pronation and supination there is some flexion and extension of the elbow and rotation of the shoulder in addition to rotation of the radius. The *oblique ligament* helps to hold the radius in contact with the humerus through the medium of the ulna. The *obliquity* of the fibers of the *interosseous membrane* (from above and without downward and inward) makes the ulna share with the radius in the strain of the latter in resting on or pushing with the palm and communicates to the radius the force imparted to the ulna in a blow from the shoulder.

**Fractures of the shafts of the radius and ulna** may be due to direct, indirect or rarely to muscular violence. *Fracture of the ulna alone*, the more superficial and exposed of the two bones, is almost invariably the result of *direct violence* such as a blow on the arm raised to protect the head, for in this position the ulna becomes uppermost. *Fracture of the radius alone* is also generally due to direct violence but is more often the result of indirect violence than fracture of the ulna, for it receives all shocks transmitted from the hand. According to Malgaigne "*green-stick fractures*" are more common in the forearm than elsewhere.

The *displacement* varies greatly with the direction of the fracture and the fracturing force so that we may find overriding, lateral or angular displacement. In some cases it is *affected by muscular action*. Thus in fracture of the radius alone above the insertion of the pronator teres the upper fragment may be fully supinated by the biceps and supinator (brevis) while the lower fragment is maintained by the splints in the usual position midway between supination and pronation. If union occurs with the fragments in these relative positions the power of *supination will be lost* as the supinators can act no further. The same result may follow after fractures of both bones. Another im-

portant *displacement* that may be *due* partly or entirely to *muscular action* in fracture of one or both bones between the two pronators is that in which the two *bones approach one another*. The upper fragments of both bones, or of the radius alone, may be drawn toward the opposite bone by the pronator teres; and the lower fragments of both or either bone may be similarly made to approach the opposite bone by the pronator quadratus and the brachioradialis. The resulting *diminution of the interosseous space* or the actual *osseous union* between the two bones interferes with or entirely prevents rotation of the radius, for the performance of which the interosseous space is essential. Excessive formation of callus may produce a similar result. Actual bony union of the two bones is more likely to occur when both bones are broken at the same level, but as a rule the radius is broken nearer the elbow than the ulna.

The upper fragment of the radius may also be drawn forward by the biceps and pronator teres. In general when only one bone is broken the other acts as a splint to prevent marked displacement, except the rotary (supination) displacement of the radius and the approach of one or both fragments to the opposite bone. In fracture of the ulna alone marked displacement of its fragments may occur in case of the not infrequent complication of dislocation of the head of the radius forward.

In treatment the following points should be observed after the *displacement is corrected* as perfectly as possible. If there is any *tendency to supination* of the upper fragment of the radius the forearm should be placed in the supine position so that after union the power of supination may be preserved. In order to *avoid* as far as possible the *union of the two bones*, and the consequent loss of rotation, the forearm should be placed in a position in which the interosseous interval is widest, *i. e.*, in the position midway between pronation and supination. The position of complete supination would serve equally well but is more irksome to the patient. With the object of preventing union between the two bones the use of graduated pads have been advised to force the bones apart by pressure. But this pressure, as well as any undue pressure of the splints and bandages, is in danger of producing *gangrene* of the limb, which is more common after fracture of the forearm than after fracture elsewhere. This is owing to the fact that most of the venous blood is returned by the surface veins which, as well as the main arteries, are readily affected by pressure.

In amputation of the forearm, the *flap method* is best suited to the *upper two thirds*, the *circular* to the *lower third*. In the latter part the soft parts are mostly skin and tendons and the bones come closer to the sides of the limb so that the flap method is unsuitable. As the soft parts divided are mostly tendons they are more easily and cleanly divided from within outward by transfixion. *Arteries and nerves divided*: Fig. 46, On the sides of the anterior or flexor aspect of the cut surface are the radial and ulnar arteries, the former no longer accompanied by its nerve, the latter with the ulnar nerve to its inner side. In

## PLATE XIX.

Upper segment of the section. (Tillaux.)

front of the interosseous membrane is the anterior interosseous artery and, with the median nerve in the posterior layer of the sheath of the flexor sublimis, is the median artery, sometimes of large size. Posteriorly between the deep and superficial layers of muscles is the posterior interosseous nerve and artery.

In the *upper two thirds* of the arm, where the muscular masses cover the bones at the sides and the limb is more flattened and conical, *amputation by antero-posterior flaps* is more suitable. The *anterior flap contains* the brachioradialis and the flexor muscles, the *posterior flap* the extensor muscles. The anterior flap is more substantial, as the bones lie nearer the posterior surface. The *radial artery* with the radial nerve run the whole length of the anterior flap and are *cut* near its outer border, internal to the brachioradialis. The *ulnar artery* is *cut* at a higher level, in front of the ulna and between the superficial and deep flexors. The anterior interosseous artery is *cut short* just in front of the interosseous membrane, the posterior interosseous is *cut long* between the superficial and deep muscles. The principal *nerves* are good *guides to the corresponding vessels*.

It may be noticed in this connection that the ulnar artery gives off the interosseous trunk one inch below the bifurcation of the brachial, which occurs opposite the upper part of the neck of the radius. As the chief pronators are the pronator teres and quadratus and the flexor carpi radialis and the chief supinators are the biceps and supinator (brevis), it follows that in amputation above the insertion of the pronator teres (the middle of the arm) the radius will become supinated and its further rotation lost.

### THE REGION OF THE WRIST.

This region may be artificially *limited*, according to Tillaux, by planes two fingers' breadth above and below the radiocarpal joint.

**Surface Markings and Landmarks.**—The *radial and ulnar styloid processes* can always be made out and are the most important landmarks for examination of or operations on the wrist. The *radial styloid process*, a finger's breadth above the thenar eminence, is more anterior and descends one half inch lower than that of the ulna. Partly on account of this fact abduction is less free than adduction of the hand. The *radial styloid* is commonly *carried upward in Colles's fracture* so as to be on a level with or above the *ulnar styloid*, a point of diagnostic importance. Just beneath the *radial and ulnar styloid processes* one enters the *radiocarpal joint*, the line of which is concave inferiorly and rises 1 cm. above that connecting the *styloid processes*. In pronation of the forearm the *ulnar styloid process* is less distinct and the bony prominence at the back of the *ulnar side of the wrist* is due to the head of the *ulnar*. The *ulnar styloid process* is most plainly felt in supination, at the inner and posterior aspect of the wrist, to the inner side of the *extensor carpi ulnaris tendon*.

In front of the wrist are several *skin creases* of which the *lowest and most distinct* is slightly convex downward and is about 1 cm.

below the radiocarpal joint (Tillaux). If the *line of this crease* is continued around the back of the wrist it crosses the neck of the os magnum in the line of the third metacarpal bone. This point is felt as a depression in extension of the wrist, but is replaced by a prominence, the head of the os magnum, in flexion of the wrist. This crease also *indicates* fairly well the *upper border* of the *anterior annular ligament*, which corresponds to the lower border of the posterior annular ligament. Above the thenar and hypothenar eminences is a slight depression which in Colles's fracture forms a marked angular depression and serves as an excellent sign of this injury, according to Tillaux. About and below the point where the flexor carpi radialis tendon crosses the lower skin crease, a bony *ridge* can be felt, formed by the *tubercle of the scaphoid* and the *ridge of the trapezium*. Corresponding to this level at the base of the hypothenar eminence the *pisiform* can be still more readily felt. Below the head of the ulna at the back of the wrist the *cuneiform bone* may be felt as a slight prominence.

**Topography. The Front of the Wrist.**—On the radial side in the *groove* between the tendons of the brachioradialis and flexor carpi radialis, which is most marked when the wrist is flexed, can be felt the *radial artery*. This is very *superficial*, lying just beneath the fascia and hence easily exposed, compressed or wounded. It is here that the *pulse* is taken and arterial sclerosis looked for. To the ulnar side of the flexor radialis tendon is the *most prominent tendon* of this region, that of the *palmaris longus*. It is made most prominent when the wrist is partly flexed, the thenar and hypothenar eminences adducted and the fingers extended. It is near the center of the wrist. In the groove between the two last named tendons, or beneath the tendon of the palmaris longus, is the *median nerve* covered by the deep fascia. As the palmaris longus is not seldom wanting the *flexor carpi radialis tendon* is the better guide to the nerve, which lies between it and the flexor sublimis. On the ulnar side the *flexor carpi ulnaris* can be felt extending to the *pisiform bone*. It is made most prominent by slight flexion of the wrist and adduction of the little finger. In the groove to its radial side, between it and the more deeply placed flexor sublimis tendons, lie the *ulnar artery and nerve*, the latter close to the ulnar side of the artery. The artery and nerve are covered by a deep and a superficial layer of the deep fascia of the forearm but pierce the deep layer, which is connected with the sheath of the flexor sublimis, just above the anterior annular ligament in order to pass in front of the latter. The *synovial sheath* for the superficial flexors and that for the long flexor of the thumb extend up the wrist above the annular ligament for  $1\frac{1}{2}$  to  $1\frac{1}{2}$  inches. (Fig. 47.) The structures above named at the front of the wrist lie upon or in front of the pronator quadratus muscle.

At the outer aspect of the wrist the outer surface of the radius is crossed by the tendons of the extensor ossis metacarpi pollicis and extensor brevis pollicis. These tendons are made very prominent by extension and abduction of the thumb, in which position they bound externally a depressed triangular space, the "*snuff box space*" or "*taba-*

## PLATE XX.

FIG. 48.

Synovial membranes of tendons on the dorsum of the forearm and hand, artificially distended. (Gerrish, after Testut.)

tière anatomique" of French writers, whose ulnar boundary is formed by the extensor longus pollicis tendon. The *floor of the space* is formed by the scaphoid and trapezium with their dorsal ligaments over which, and beneath the above tendons, runs the *radial artery* in its course from just below the apex of the styloid process to the back of the first interosseous space. The artery is here *covered by two layers of fascia* the deeper of which holds it close to the carpal bones. Subcutaneously the radial vein and branches of the radial nerve cross this space, the latter vertically, so that *incisions* to reach the artery should be *made vertically*. The *tendons* which cross the outer and dorsal surfaces of the lower end of the radius *occupy grooves bounded by ridges* of which that on the radial side of the groove for the extensor longus pollicis is prominent subcutaneously. The groove for this tendon indicates the center of the combined dorsal and external surfaces of the radius and corresponds about to the interval between the scaphoid and semilunar bones. Between the two grooves for the extensors of the thumb is one, sometimes divided by a low ridge, for the short and long radial extensors of the wrist.

On the *dorsal surface of the wrist* on the ulnar side of the extensor longus pollicis is a shallow groove for the extensor communis and extensor indicis, next to this and between the two bones a groove for the extensor minimi digiti and between the head and styloid process of the ulna a groove for the extensor carpi radialis.

The order and relations of the *tendons* at the wrist are given in detail as they are not infrequently severed in wounds and require *tendon suture*, for which an accurate knowledge of their position and relations is essential, though when necessary the distal part of a tendon may be grafted onto another muscle with good results.

The *six grooves*, for the tendons at the back and outer side of the wrist, are converted into as many *osseoponeurotic canals* by the *posterior annular ligament*, which binds down the tendons and prevents their displacement in hyperextension of the wrist. This ligament is continuous with and a thickening of the fascia of the dorsum of the forearm and hand. In these six canals the *tendons* are surrounded by *synovial sheaths*. (Fig. 48.) The *sheaths* of the three carpal extensors and the extensor ossis metacarpi pollicis extend to or nearly to the insertion of their tendons, that of the extensor indicis is very short, the sheaths of the other tendons extend a varying distance onto the dorsum of the hand. All the *sheaths begin above* near the upper border of the annular ligament except those of the radial extensors which commence a little lower down. The sheath of the extensor ossis metacarpi and extensor brevis pollicis is the one most often inflamed in the so-called *teno-synovitis crepitans*. This is accompanied by swelling, pain and crepitation on motion and is due to injury or unusual use of those muscles.

**The Wrist Joint.**—The *strength* of the radiocarpal, or wrist joint, depends upon the number of *strong ligaments and tendons* that surround it, the absence of a long lever on its distal side and the nearness of the numerous small bones and joints of the hand among which movements

and shocks are distributed. *Its movements* are largely supplemented by those of the mediocarpal joint. In the wrist joint proper extension is most free and its *strongest ligament* is the anterior which limits hyperextension. It is noteworthy that the commonest injury is from forced extension, for in falls one naturally falls upon the palm, the wrist being extended, rather than upon the dorsum, the wrist being flexed. The *dorsal ligament* is so *thin and superficial* that swelling is first noticed at the back of the wrist in effusion into the joint. In *disease of the joint* the latter is held midway between flexion and extension as the tendons at the front and back balance one another. If the wrist joint is injected one notices, especially on the dorsum, little hernial protrusions of the synovial membrane from which are derived most of the **ganglia** which are so common in this situation. At first these communicate with the joint, but as a rule this communication becomes obliterated as the pedicle becomes lengthened. This pedicle may often be followed by dissection as a fibrous cord connecting the ganglion with the surface of the joint capsule. Similar protrusions are to be found on the synovial sheaths of the tendons, but these are much less often the starting point of ganglia.

**Dislocations of the wrist** are *rare*, for in the common form of violence, due to a fall on the palm, the joint is protected by the strong anterior ligament and fracture of the lower end of the radius almost invariably results. The dislocation is *usually forward*, less often backward, of the carpus on the forearm. It is usually *due to great violence* and hence is *often compound* and sometimes complicated by rupture of tendons or fracture of adjacent bones. I have recently seen a compound backward dislocation in which the semilunar bone projected forward through the anterior wound, and was almost entirely detached. Both forms may be due to violence applied to the flexed or extended wrist. The *deformity of backward dislocation* closely resembles that of *Colles's fracture* but in the former the swelling in front of the wrist extends further down and ends more abruptly, that at the back of the wrist is more sharply outlined at its upper border. In addition the hand is usually more flexed and less movable in dislocation.

In the **inferior radioulnar joint** the *triangular fibrocartilage* is the principal ligament and the strongest ligamentous connection between the two bones. The synovial cavity of this joint is usually separate from that of the radiocarpal joint. *Dislocation* of this joint, apart from that sometimes observed in connection with Colles's fracture, is very *rare*. It is usually forward or backward of the ulna. In the latter form it is usually due to exaggerated pronation, so that the hand is pronated and supination is interfered with. The forward form has been due to direct violence and the wrist may be pronated or supinated and rotation is difficult. The *ulna is prominent* at the front or back of the wrist according to the form of dislocation. Some surgeons have thought that the injury described above (p. 180) as subluxation of the head of the radius in young children is a dislocation of the lower end of the ulna.

**Colles's fracture** is one through the lower end of the radius from  $\frac{1}{2}$  to 1 inch above its articular surface, at or near the point where the compact tissue of the shaft joins the cancellous tissue of the lower extremity, which appears to be a weak spot. It is *one of the commonest fractures* and is most frequent in the elderly. The *direction* is transverse, usually with a slight obliquity upward and backward and sometimes with a moderate slant upward and outward. The lower fragment usually shows a moderate backward *displacement* with considerable backward and often some outward rotation. Thus the articular surface looks downward and backward instead of downward and forward as normally. *Impaction* of the upper fragment into the cancellous tissue of the dorsal and lateral part of the lower is the rule, and *comminution* of the lower fragment is frequent. In addition the *ulnar styloid process* may be fractured by avulsion by means of the internal lateral ligament rather than by the fibrocartilage.

The **deformity** in typical cases is *characteristic*. The prominence on the dorsum over the lower fragment, due to its backward displacement and rotation and to swelling, gave origin to the name, given by Velpeau, "*silver fork fracture*," on account of the resemblance of its outline as seen from the radial side. The end of the *ulna* is *very prominent in front* on account of the displacement upward, backward and somewhat outward of the lower fragment of the radius and of the carpus which preserves its relations with it. The prominence in front over the lower end of the upper fragment is mostly due to swelling of the soft parts. The *radial styloid* is *displaced* up to or above the level of the *ulnar styloid* and the transverse creases in front of the wrist are deepened. Crepitus and abnormal mobility are not present in cases with marked impaction and may not be easily recognizable in other cases.

The *cause* of Colles's fracture is almost always a fall upon the palm of the hand. The **mechanism** is neither simple nor constant and has been and is still much disputed. (1) The fracture is due to a crushing of the cancellous tissue between the carpus and the shaft, the weight of the body being received in the long axis of the radius while it is within  $30^{\circ}$  of the vertical. (2) The axis of the radius being more oblique and not in line with the fall the force is decomposed, part of it passing up the shaft in the long axis of the radius and part acting transversely to break the bone at its weakest point. The backward rotation and displacement of the lower fragment indicates the direction of this latter part of the force. (3) The fracture is due to a cross-strain exerted on the lower end of the radius through the strong anterior ligament, made tense by hyperextension of the hand. The bone is broken by avulsion on the principle that a stout ligament is stronger than cancellous bone, so that the latter gives way first. Most fractures are probably produced in one or the other of the first two ways. There is no doubt that it can be and sometimes is produced by avulsion. This theory rests upon experiments on the cadaver and is supported by many French and German writers on surgical anatomy (Tillaux, Joessel, etc.).

**Epiphyseal separation** is probably more often due to this mechanism. The *epiphysis joins the shaft* in the twentieth year; it *includes* the insertion of the brachioradialis and the facet for the ulna. The *line of the epiphyseal cartilage is nearly horizontal* and may be intra-synovial internally. Arrest of growth of the radius has followed epiphyseal separation in young subjects.

*Complete reduction* of the displacement in Colles's fracture is often difficult but is essential to prevent permanent deformity and to insure perfect function. It is noteworthy that the X-ray shows a decidedly lower position of the articular surface of the radius as compared with that of the ulna in the female than in the male.

**Amputation at the wrist joint** is *rarely performed*. Its principal object is to save the movements of pronation and supination. In most cases of injury it will either be necessary to amputate higher or it will be possible to save more, even a finger, which is most desirable. In cases of disease the necessary skin covering is involved and the movements of rotation are often lost from the disease. In general, amputations in which the bones are left covered with cartilage are objectionable, as the latter has almost no reparative action. The *elliptical method*, resembling that by long palmar flap, is the best. In it the cicatrix is dorsal, the stump is covered by the tough and well-nourished tissues of the palm and the styloid processes are well covered. The great *retractability of the skin on the dorsum*, due to the looseness of the subcutaneous tissues, should be remembered. Disarticulation is easier from the dorsum. The *radial artery* is cut at the outer end of the dorsal wound, the *ulnar* at the inner end and the *superficialis volee* at the outer portion of the palmar flap.

**Excision of the wrist** includes the removal of the carpal bones and usually the articular ends of the bones of the forearm and metacarpus. As the joints are covered and protected by strong tendons which move the wrist and fingers and which (save those of the palmaris longus and flexor carpi ulnaris) are surrounded by synovial sheaths, the *incisions* are planned so as to spare these tendons and their sheaths as far as possible. Including that of the pisiform there are *seven separate synovial sacs* in the joints of the wrist and carpus. It is *important to spare* the radial artery which is close to the first carpometacarpal joint (dorsally) the deep palmar arch (see p. 197) and if possible the annular ligaments. In *Ollier's method* the dorsoradial incision is along the radial border of the extensor indicis tendon, between it and that of the extensor longus pollicis, the *ulnar incision* is along the inner side of the extensor carpi ulnaris. The pisiform bone may usually be left and the trapezium should be when possible. Unless the subperiosteal method is employed, and this is often difficult, the tendons of the extensors and flexors of the carpus are severed or detached. Another simple and satisfactory method is to split the hand between the second and third metacarpal bones, between the trapezius and os magnum and between the scaphoid and semilunar by an *incision* between the extensor indicis and the extensor communis tendons.

### THE HAND AND FINGERS.

**Surface Markings and Landmarks. Palmar Surface.**—Between the *thenar eminence* on the radial side and the *hypothenar eminence* on the ulnar side is the “*hollow of the hand*,” a concavity of a somewhat triangular outline. Its apex is above and it is limited below by three little elevations opposite the clefts between the fingers. These elevations are due to the projection of the fatty tissue between the flexor tendons and the digital slips of the palmar fascia, which form the grooves between these elevations. The hollow of the hand is more marked in the position of flexion and in muscular subjects. The bony prominences at the proximal ends of the thenar and hypothenar eminences have already been referred to.

FIG. 49.

Position of the principal creases of the palmar surface and of the palmar arches.

Three of the many creases in the skin of the palm deserve notice. The first marks off the *thenar eminence* from the hollow of the palm. It starts at the wrist and ends at the radial border of the palm at the base of the index finger. The second starts on the radial border, at

or just below the last, and crosses the palm obliquely inward and upward to the hypothenar eminence. The third and lowest starts from the elevation opposite the cleft between the first and second fingers and runs obliquely to the ulnar border. The first is due to the opposition of the thumb, the second to the flexion at the metacarpo-phalangeal joint of the index and middle fingers, the third to the similar flexion of the inner three fingers. Topographically the second fold, where it crosses the third metacarpal bone, is just below the lowest point of the superficial palmar arch, and the third fold crosses the necks of the metacarpal bones, roughly indicates the upper limit of the synovial sheaths of the middle and ring fingers, and lies a little above the division of the palmar fascia into its digital slips. The metacarpophalangeal joints lie about midway between this fold and the webs of the fingers.

The uppermost of the folds across the front of the fingers separate them from the palm, and are on a line with the webs of the fingers and 12–15 mm. below the metacarpophalangeal joints. The upper of the middle series of folds are opposite the first interphalangeal joints and the lowest set of folds are  $2\frac{1}{2}$  mm. above the second interphalangeal joints. On the thumb the two creases correspond to the two joints, the upper crease crossing the joint obliquely.

**Dorsal Surface.**—The proximal ends of the first and fifth metacarpal bones are prominent and can be readily felt. A line slightly concave downward, joining the upper ends of these and 1 cm. below the lowest skin crease in front of the wrist, indicates the line of the carpometacarpal joints. When the fingers are flexed, the prominences

of the knuckles are formed by the proximal bone of each joint (Fig. 50), so that the joint line lies below the prominences by one twelfth inch in the distal, one sixth inch in the middle and one third inch in the proximal joints. The first dorsal interosseous muscle forms a prominence between the first and second metacarpal bones, when the thumb is adducted.

The skin of the palm and of the palmar surface of the fingers is thick and dense and without hairs or sebaceous glands. Beneath the epidermis, which is particularly thick, small subepidermal abscesses often develop. The skin of the dorsum of the hand is much thinner and down to the second or third phalanges is supplied with numerous hairs and sebaceous follicles and hence is liable to furuncles and other lesions associated with these structures. The skin of the palm is more abundantly supplied with sweat glands than any other part of the body, four times more so, according to Sappey. Hence the profuse perspiration that may occur here, as is well known. The Pacinian bodies and tactile corpuscles in connection with the free cutaneous nerve supply are more numerous on the palmar aspect than elsewhere in the body. The palmar aspect of the third phalanx, especially that of the index finger, is most sensitive and, with the exception of the tip of the

FIG. 50.

Outline to show the relation of the bent knuckles to the joint lines. The shaded portions represent the epiphyses.

tongue, possesses more acute tactile sensibility than any other part. *The dorsum* of the hand, on the contrary, is *but little sensitive* to tactile sensation. The area around the upper end of the nail is liable to superficial subepidermal abscesses ("run around," *paronychia*) which develop quickly.

**The subcutaneous tissue** on the palmar aspect intimately connects the overlying skin with the underlying fascia in the palm, and with the tendon sheaths in the fingers. Hence subcutaneous inflammatory or bloody extravasations and oedema are practically impossible here, while *on the dorsum*, where the subcutaneous tissue is *lax and abundant*, swelling and oedema may be very marked. For the same reason *wounds* do not gape on the palmar surface but gape widely on the dorsum. The denseness of the skin and underlying parts on the palm renders inflammation very painful on account of the tension caused by the inflammatory products, while on the dorsum the reverse is the case. Another particular in which the *coverings of the palm resemble the scalp* is in the arrangement of the subcutaneous fat, the lobules of which are contained in small fibrous compartments of the subcutaneous tissue. This arrangement of the skin and underlying tissues of the palm *adapts it to resist the effects of pressure and friction*. Thus the ulnar border of the palm is much used in resting on the hand and in hammering movements, and it is noteworthy that the soft parts here are singularly free from large nerves. The palmar aspect is singularly *free from large surface veins*, which are abundantly found on the dorsum of the hand. The *lymph vessels*, on the contrary, are more numerous on the palmar surface of the hand and fingers.

**The palmar fascia**, *in its central portion* beneath the hollow of the palm, is *very dense and thick* and is *triangular* in form. *Its upper end* is connected with the lower border of the annular ligament and of the palmaris longus, of which it is the degenerated distal end. Its lower end or *base splits into four slips* which join the fibrous tendon sheaths of the fingers and send fibers to the skin, and deep transverse ligaments. The digital vessels and nerves and the lumbrales emerge in the interval between these slips. The denseness of the fascia well protects the soft parts beneath.

**Dupuytren's contracture** is a peculiar *contraction of the palmar fascia* and its slips, especially those going to the *ring and little fingers*. It occurs especially in men after middle life and may be associated with traumatism. It gradually flexes the first and then the second phalanges onto the palm. The tendons are not involved but between them and the thickened projecting cord-like slips of fascia, which are connected with and wrinkle the skin, is a layer of fatty connective tissue.

**Laterally the palmar fascia** is continued as a thinner layer over the thenar and hypothenar eminences. A fibrous membrane connects the deep surface of the palmar fascia, on each side of the central portion, with the interosseous fascia covering the palmar interossei. In this way *two lateral (thenar and hypothenar) and a central compartment*

*ment* are formed. Suppuration commencing in any of these spaces may be limited to that space for a time but the membranous septa are thin and may soon yield. The *central compartment* is continuous above, beneath the annular ligament and along the flexor tendons, with the wrist and forearm. It is continuous below with the sheaths of the flexor tendons and the three intervals between the digital slips of the fascia which correspond to the webs between the fingers. Hence *pus in the central compartment* of the palm makes its way up into the forearm or down along or between the fingers. The resistance offered by the palmar fascia is so firm that rather than perforate it pus makes its way through the interosseous spaces to the dorsum, though this course is resisted by a layer of fascia covering the deep palmar arch and the interossei muscles. This fascia joins the membranes separating the central compartment of the palm from the thenar and hypothenar compartments in front of the third and fourth metacarpal bones respectively.

Practically *abscesses of the palm* may be divided into those in front of and those behind the palmar fascia. *Abscesses in front of the fascia*, whether subepithelial or subcutaneous, are small, confined to the palm and very painful, but the pain is limited to the palm. *Subfascial abscess* may spread to the fingers, wrist and forearm or to the dorsum, which is usually much swollen. The pain is intense and is felt along the course of the nerves. In *opening abscesses of the palm* and in all operations on the palm the *incision* should be *vertical*, parallel with the tendons and digital nerves and above or below the superficial palmar arch (see p. 197). If an *incision* is required in the *wrist* it should be vertical and to the ulnar side of the palmaris longus tendon, where it will avoid the ulnar and radial arteries and the median nerve.

The *fibrous sheaths of the flexor tendons* extend from the metacarpophalangeal joints to the upper ends of the last phalanx at the insertion of the profundus tendons. There being no intervening fascia here, the skin and subcutaneous tissues are connected with these sheaths in the same intimate way as with the fascia in the palm. The sheaths arch across the front of the phalanges between their lateral margins and thus form semicylindrical canals which lodge the synovial sheaths. The fibrous sheaths are dense and rigid so as to remain open when cut, so that in amputation of the fingers an open channel leading up to the palm is left for the spread of infection. Opposite the joints of the fingers the sheaths are thin and lax, leaving spaces between their obliquely decussating fibers through which the synovial lining may protrude and suppuration may find its way into the interior of the sheath.

**Two synovial tendon sheaths** are found in the palm, *the outer* for the flexor longus pollicis, *the inner* for the superficial and deep flexors of the fingers. These extend up beneath the annular ligament, where they are constricted, and for about  $1\frac{1}{2}$  inches above it into the wrist. Inferiorly the outer one extends to the insertion of the flexor longus pollicis, the inner one to the insertion of the flexor profundus of the

PLATE XXI.

FIG. B1.

Tendon sheaths and muscles of the palmar surface  
of the left hand. (Joessel.)

little finger and to about the middle of the metacarpal bone for the other three fingers, but further down on the tendons of the ring finger than on those of the other two. On the ring, middle and index fingers the *digital synovial sheaths* commence opposite the heads of the metacarpal bones and extend to the insertion of the profundus tendons, being contained within the fibrous sheath. (Fig. 51.) They are thus separated by one fourth to one half inch from the main palmar synovial sheath of the flexor tendons. Hence operations on and inflammation of the thumb and little finger are more serious than of the other fingers, for inflammation in the former may more readily spread to the synovial sac of the palm, causing a swelling here, which is constricted beneath the annular ligament and is expanded again in front of the wrist. This is seen, not infrequently, in case of felon of these two fingers. As the two sheaths may communicate normally or pathologically inflammation may spread from the thumb to the little finger or vice versa, giving rise to a horseshoe-shaped swelling. The two palmar sacs may be the seat of cysts which show the characteristic form of the sacs. In case of tubercular inflammation here and in the sheaths of the extensor tendons at the back of the wrist the sheaths are filled with fibrinous masses known as rice bodies.

The **superficial palmar arch** (Fig. 49) lies beneath the palmar fascia and superficial to the flexor tendons. Its *course* is represented by a line, slightly convex downward, commencing at the radial side of the pisiform bone and crossing the palm in line with the palmar aspect of the thumb, when abducted at right angles with the index finger. This line should be avoided if possible in *incisions* in the palm. The **deep arch** (Fig. 49) lies about one half inch nearer the wrist, in front of the bases of the metacarpal bones, and beneath the deep or interosseous fascia. It is nearer the dorsal than the palmar surface and is more liable to injury from the former aspect. The *bifurcation of the digital arteries* occurs about one half inch above the webs of the fingers.

The *blood supply of the fingers* is very abundant, the pulp of the fingers being one of the most vascular parts of the body. It is owing to this fact that in so many cases the tip of the finger, accidentally cut off, has grown on again when reapplied at once.

**Wounds of the palmar arches** and their branches are serious on account of the *difficulty of checking the hemorrhage*. This is due to the danger of damaging important structures of the palm and to the free anastomosis, whereby ligature of either the radial or ulnar or both does not control the bleeding, for the arches anastomose with each other and with the carpal arches, which communicate with the two interosseous vessels above. Hence the two ends of the divided artery should be secured if possible but, if the wound is deep or narrow, pressure may often arrest the bleeding. The possibility that pressure may cause gangrene, owing to the rigidity of the parts, should be borne in mind.

Beneath the superficial arch and superficial to the flexor tendons is the **median nerve** in the groove between the long flexor of the thumb

and the flexors of the fingers. The **nerve supply** of the hand and fingers is of interest and practical importance.

**Cutaneous Nerve Supply** (Figs. 52 and 53). **Palmar Surface.**—The palm is supplied by the median and ulnar nerves which anastomose with one another. The palmar aspect of the little and the ulnar side of the ring finger are supplied by the ulnar, that of the other fingers by the median. On the dorsum of the hand the radial and ulnar nerves supply its radial and ulnar sides respectively, and anastomose with one another. The dorsal aspect of the thumb is supplied by the radial nerve as is that of the index and the radial side of the middle finger, as far as the second phalanx. The dorsal branch of the ulnar nerve supplies the dorsal aspect of the little, ring and ulnar side of the middle fingers as far as the second phalanx. In some cases the contiguous halves of the dorsum of the first phalanx of the ring and middle finger is supplied by the radial nerve or partly by the radial and partly by the ulnar. The dorsal aspect of the second and third phalanges of the four fingers are supplied by branches from the nerves supplying their palmar surfaces.

The occasional apparently contradictory results of nerve lesions are due to the above mentioned variation (on the ring and middle fingers) and to the anastomoses between the nerves on the dorsal and palmar surfaces of the hand. Thus the loss of sensation is often quite slight in comparison to the area supplied and the same facts, and not "immediate union," probably explain the cases where sensation has returned within a few hours after suture of one of the nerves.

**Motor Nerve Supply.**—*The ulna* supplies the interossei, adductor pollicis, inner head of the flexor brevis pollicis and the two inner lumbricales, as well as the muscles of the hypothenar eminence and the inner half of the flexor profundus. Hence **paralysis of the ulnar** is followed by inability to adduct the thumb (adductor), to flex the last phalanx (profundus) or the first (interossei) of the two inner fingers, or to extend their last two phalanges (interossei). The latter two fingers are therefore held in the position of extension of the first phalanx (common extensor) and flexion of the second phalanx (flexor sublimis). The muscles of the hypothenar and ulnar part of the thenar eminence are paralyzed and become atrophied.

As the **median nerve** supplies the rest of the long flexors and those thumb muscles not supplied by the ulnar, and also the two outer lumbricales, its **paralysis** is followed by inability to flex the second phalanx of all fingers, the last phalanx of the middle and index fingers, to flex or abduct the thumb, to pronate the hand and to flex the wrist, except by means of the flexor carpi ulnaris. The thumb is held adducted and extended. Flexion of the first phalanges with extension of the last two can be performed in all fingers by means of the interossei.

On the dorsum of the hand the **extensor tendons** are united together by connecting slips so that it is difficult to extend one without the neighboring finger. The index finger can be extended alone most readily, next the little finger, for they are joined by only one band to

PLATE XXII.

(W. Keiller.)

the tendon of the neighboring finger. The ring finger is extended alone with the most difficulty. The extensor tendons serve the place of posterior ligaments for the three joints of the fingers. When the last two phalanges alone are flexed, the first is steadied by the extensor tendons so that in paralysis of the latter this movement is not possible. When a finger is torn out it takes with it one or more tendons, most often the flexor profundus tendon if only one is avulsed.

**Felon or whitlow** is an inflammation usually commencing on the palmar aspect of the terminal phalanx, in the soft parts, tendon sheaths or periosteum. However it begins, unless it is promptly incised, it is liable to extend to the synovial sheath of the tendon or to the periosteum. The latter is readily attacked as it is not covered by the tendon sheath beyond the base of the terminal phalanx. As the result of the involvement of the periosteum the bone often necroses, but usually only the terminal part for the base, which is an epiphysis not uniting with the shaft till about the eighteenth year, is protected by the insertion of the flexor profundus tendon. When the synovial sac is involved the abscess extends to the end of the sac opposite the head of the metacarpal bone, except in case of the thumb or little finger in which it may extend into the palm, beneath the annular ligament and up into the wrist, etc. (see p. 196).

**Bones and Joints.**—In fracture of the metacarpal bones but little displacement is allowed as they are splinted to the neighboring bones by the interosseous muscles. The carpometacarpal joints of the first three fingers allow of but little motion, that of the little finger and especially that of the thumb allow more free motion. The preservation of these joints is of great importance to the usefulness of the hand. Under all circumstances as much of the thumb as possible and a portion of the fingers or hand, to oppose it, should be saved, to preserve the forceps or grasping function of the hand.

**Dislocations of the metacarpophalangeal and interphalangeal joints** are common. Dislocation of the first phalanx of the thumb backward is the most important on account of its common occurrence and the frequent difficulty in its reduction. The latter has been explained in many ways; the button-holing of the head of the metacarpal bone between the two sets of muscles which center in the sesamoid bones, the entanglement of the long flexor tendon around the neck of the metacarpal bone, the intervention of the anterior glenoid ligament between the two joint surfaces, etc. The latter explanation is thought by Farabeuf to cover most cases. The glenoid ligament is torn from the metacarpal bone, to which it is loosely attached, but remains fixed to the phalanx and is carried back with it. If now the thumb is straightened, as it may be, and traction is made in this position the muscles attached to the sesamoid bones pull the ligament back and if the phalanx is brought back into place by traction, the glenoid ligament lies between the joint surfaces with its anterior face applied to the head of the metacarpal bone. In any case traction in the straightened position should never be employed in reduction for fear of changing a

simple into a "complex dislocation," but rather traction in the hyper-extended position. According to Stimson the resistance to reduction is due to the torn edges of the anterior ligament drawn closely across the metacarpal bone behind its head. This condition is frequently found on arthrotomy performed to reduce the dislocation, and a slight nicking of the tense edge makes reduction easy.

As it is important to know *from which spinal nerves* the various *nerves of the arm spring* and the muscles supplied by them are innervated, for the purpose of diagnosis of nerve injuries of the upper limb, the following table is added.

**Nerves.**—Suprascapular nerve and circumflex, 5, 6, C.; posterior thoracic (nerve of Bell) and musculocutaneous, 5, 6, 7, C.; internal cutaneous and ulnar, 8, C., 1, D.; lesser internal cutaneous (nerve of Wrisberg), 1, D.; musculospiral, 5, 6, 7, 8, C.; median, 6, 7, 8, C., and 1, D.; nerve to rhomboids, 5, C.; nerves to subscapularis and teres major (upper and lower subscapular), 5 and 6, C.; nerve to latissimus dorsi (middle or long subscapular), 7 and 8, C.

The entire *brachialplexus* may be ruptured or, more commonly, torn away from its attachments to the cord, or one or more of its cords, primary divisions or branches may be torn, stretched or compressed. The **cutaneous distribution** of the nerves of the arm is shown in the accompanying cuts.

## CHAPTER III.

### THE THORAX.

#### I. THE THORACIC WALLS.

**Shape and Size.**—The *adult thorax*, covered by the soft parts, appears *conical*, with its base above and its apex below and flattened from before backwards. Its *circumference* at the apex of the axilla is considerably greater in the male than that at the level of the nipple or at the base of the xiphoid process. In the female the circumference at the nipple is nearly as great as that at the axilla and the latter is considerably less than the similar measurement in the male. In the *phthisical* the upper circumference is less than the lower (Hirtz). The *senile thorax* is narrowed above and lengthened so as to be conical with the base below. This is due to a sinking of the front of the ribs, due to the relaxed tone of the muscles. In the *fœtus* it is flattened laterally, the antero-posterior diameter being the greater. In the *infant* at birth the thorax is short, nearly circular on cross section and conical, with its base below. These differences in the infant are due, respectively, to the more horizontal position of the ribs, the absence of the angles of the ribs and the greater size of the liver, as compared with the lungs.

The *vertical diameter* of the posterior wall is over twice that of the anterior wall in the median line (31.5 cm. to 15.5 cm.) and the vertical diameter of the side of the thorax is longer than that of the posterior wall. The *height* of the thorax increases with that of the body but not proportionally, the *transverse diameter* increases less and the *antero-posterior diameter* still less. The greater height of the body is largely due to the length of the lower extremities. However a too small circumference of the thorax in a tall subject is thought to indicate a predisposition to phthisis. In the Prussian army those whose chest circumference is less than half the body height are regarded as narrow-chested and predisposed to tuberculosis unless the chest is widened by drill. The *thorax of the female* is relatively smaller than that of the male, is less flattened and more rounded. The two halves of the thorax are usually *unsymmetrical*, the right measuring more (1 to 1½ cm.), owing to the greater use of the right side.

When the soft parts covering it have been removed the thorax is seen to be conical in shape with the apex above. Hence the lung capacity is not indicated by the breadth of the shoulders but rather by the size of the base of the neck.

**Abnormal and Pathological Forms of the Thorax.**—Occupation may affect the shape as by the pressure of tools depressing the ster-

num and flattening the thorax. *Corsets* may so press in the lower ribs as to make the thorax spindle-shaped, or even smaller below than above. In *pigeon breast* the sternum and costal cartilages are protruded in relation to the ribs, like the sternum of a bird. It occurs especially in rickety children, in whom the long bones are not properly ossified, particularly at their epiphyseal junction, as at the costochondral. In such a case there is often obstruction in the respiratory passages, due to adenoids or hypertrophied tonsils, so that in inspiration the air can not enter the chest fast enough to make the air pressure within equal to the atmospheric pressure without the thorax. Hence the weakest part, or that along the costo-chondral line, is pressed inward, making the sternum relatively prominent. In rickets the enlargement of the ends of the ribs along this line is often palpable and sometimes visible, receiving the name of "*rickety rosary*."

Two opposite pathological types of thorax may be distinguished. **The emphysematous type** or *the type of permanent inspiration* is like that seen in pulmonary emphysema. The chest is barrel-shaped, enlarged in circumference but shortened vertically. As it is in the position of inspiration at all times the capacity of the chest can not be much increased. An approach to this type is normal as adult life advances. **The type of permanent expiration** or *the phthisical type* (*habitus paralyticus*) is the opposite of the above. The chest appears flattened and lengthened. It may predispose to phthisis or be the result of it. The upper part of the thorax is especially contracted.

Again in anterior and lateral curvatures of the thoracic spine the thorax is deformed. In *anterior curvature of the spine* (usually the result of Pott's disease) the sternum is thrust forward and the ribs are more oblique, approaching the pelvis so that the free ribs overlap the iliac crests. In *lateral curvature* the ribs on the convex side of the curve are more separated from one another than normal, those on the concave side more pressed together and sometimes so depressed as to touch or even overlap the iliac crests. Owing to the rotation of the vertebrae the ribs on the convex side bulge posteriorly on account of the prominence of their angles, and the scapula is carried back with them, making a "hump" on that side. On the concave side, usually the left, the front of the chest is abnormally prominent. As a result of pleuritic or pericardial effusions, aneurism, tumors, etc., the *thorax* may become *protruded* and it may become *sunken in* from retraction of an adherent lung, etc. Such protrusions and retractions may involve a part or the whole of one half of the thorax.

**The internal configuration** of the thorax is somewhat *heart-shaped* owing to the forward projection of the vertebral bodies, which renders the internal sagittal diameter but 1 cm. more than one half the same measurement externally. Owing to the backward projection of the angles of the ribs and the fact that the line of gravity descends in the cord of the backward curve of the thoracic vertebrae there is nearly as much space within the thorax behind the line of gravity as there is in front of it. Hence the erect position is easily maintained without

the excessive muscular action which is necessary in animals in which these conditions do not prevail. Furthermore, in the human subject, the backward projection of the angles of the ribs on either side to about the level of the vertebral spines renders possible the supine position, which is not possible in animals, as in them the spines project mesially without the corresponding lateral projection of the ribs.

The thorax is bounded in front by the sternum, costal cartilages and the spaces between them, laterally by the ribs and intercostal spaces, behind by the thoracic vertebrae and the posterior ends of the ribs and intercostal spaces. The bony thorax covers several of the abdominal viscera in addition to the thoracic, hence, besides the thoracic cavity proper, it bounds part of the abdominal cavity, the two being separated by the obliquely placed diaphragm (see p. 212). The latter therefore forms the convex floor of the thoracic cavity proper. The apices of the lungs and pleural cavities extend through the small superior aperture of the thorax, as well as the trachea and oesophagus and the vessels, nerves and muscles which pass between the neck and thoracic cavity. This superior aperture connects the neck and thoracic cavity. It is formed by the first ribs, first thoracic vertebra and the top of the sternum, is kidney-shaped, and slanted slightly downward from behind forward. It measures  $2\frac{1}{4}$  inches from behind forward and  $4\frac{1}{4}$  transversely.

To assist in the topography of the chest we distinguish certain vertical lines in addition to the median line, i. e., the sternal line along the side of the sternum, the mammary line through the nipples, the axillary line midway between the anterior and posterior axillary lines, which are drawn through the lower ends of the anterior and posterior axillary folds, and the scapular line drawn through the inferior angle of the scapula. The parasternal line is midway between the sternal and mammary lines and the costoclavicular line connects the sternoclavicular joint with the tip of the eleventh rib.

**Landmarks of the Thoracic Walls.**—In the median line anteriorly the top of the sternum corresponds to the cartilage between the second and third thoracic vertebrae, the junction of the manubrium and body of the sternum is indicated by a readily palpable, prominent, transverse ridge which is continuous with the second costal cartilages. This is the easiest and most reliable point to start from in counting the ribs. It corresponds to the lower part of the fourth thoracic vertebra. The junction of the body and ensiform process of the sternum is readily palpable as a ridge, for the ensiform is at a deeper level than the sternal body. This junction corresponds to the articulation of the seventh costal cartilage with the sternum, and to the ninth thoracic vertebra behind. It is also on a level with the lowest point of the fifth rib.

Laterally the nipple lies on a level with the anterior end of the fourth rib (Hyrtl), or in the fourth space, nearly one inch external to the costal cartilages. The virgin breast covers the ribs from the third to the sixth. The lowest point of the seventh rib (the junction of the rib and costal

cartilage) lies in the mammary line. The costochondral junction of the ribs above the seventh lie internal to this line, that of the lower ribs external to this line, in an oblique line extending downward and outward. The lower border of the pectoralis major corresponds to the fifth rib, the first visible serration of the serratus magnus to the sixth rib. *Posteriorly* the scapula covers the ribs from the second to the seventh (sometimes the eighth). Owing to the obliquity of the ribs we find in a sagittal section in the mammary line that the first rib in front corresponds to the fourth rib behind, the second to the sixth, the third to the seventh, etc., each rib below the first in front corresponding to the fourth one lower in the series behind.

**The Layers of the Thoracic Wall.**—The skin over the sternum is a favorite locality for *keloid growths*. Gummata are also often found in the soft parts covering the sternum, especially the periosteum. The subcutaneous tissue of the thoracic wall may be the seat of extensive *emphysema* in some fractures of the ribs or in perforating wounds of the thorax.

**The sternum** is very variable in *length* and is often not in proportion to the height of the body. I have seen the sternum  $10\frac{1}{2}$  inches long in a man of average height. In women the sternum, and especially its body, is relatively shorter than in men. The holes or clefts in the lower part of the sternum, due to defects in its development from two lateral halves, may give pus an entrance to or an exit from the mediastinum. After a median division of the sternum the two halves may be retracted so as to expose the great vessels in the mediastinum for ligation. It may be trephined to open mediastinal abscess or for pericardial paracentesis.

The sternum may be *fractured* by *direct violence*, as by the violent contact with the chin, or by *indirect violence*, as by the traction of the muscles when the body is forcibly bent backward. The fracture is usually transverse and occurs most often at or near the juncture of the manubrium and body, near the narrowest part of the bone. The body of the sternum with the ribs is commonly *displaced* forward. The lesion is often a *dislocation* in whole or in part through the joint between the manubrium and body. In old age when this joint is ossified the tendency to fracture is increased by making the chest more rigid. Fracture of the sternum is *not common* owing to the elasticity of the ribs and costal cartilages which support it, the elasticity of the sternum which is formed of two parts articulated together at a slight angle, and the soft cancellous character of the bone. The cancellous structure accounts for its being often attacked by caries and for its ready absorption from the pressure of an aneurism.

The tip of the *ensiform cartilage* may bend forward or backward. The ensiform often presents median apertures and it, as well as its articulation with the sternum, may become ossified in advanced age. The *costal cartilages* by their *elasticity* increase the resistance of the sternum and ribs to injury. When they become *ossified* in advanced age the ribs and sternum are more exposed to fracture. They in-

crease in *obliquity* from the third down, and in *length* down to the seventh. When the ribs are raised in inspiration the costal cartilages are raised and become more horizontal. This throws the ribs outward, increasing the transverse diameter of the thorax. When inspiration is completed their *resiliency* brings them, and with them the ribs, into their normal position so that quiet expiration requires no muscular action. At the border of the sternum only the first two or three interspaces between the costal cartilages are wide enough to operate through, as in ligature of the internal mammary artery. Below this the spaces are so narrow that resection of the cartilages is necessary to expose the parts beneath.

**The ribs** increase in *obliquity* from above downwards. They increase in *length* as far as the seventh, and thence they decrease. The *raising* of the ribs in inspiration shortens the thorax but increases the antero-posterior and the transverse diameters. The latter diameter is also increased by the throwing out of the ribs at the side, in the *rotation* that occurs on an axis passing through their two articulations. This rotation accounts for all the movements of the ribs.

The ribs are unequally exposed to injury. The upper ribs, first and second, are protected by the overlying pectoral muscle and the clavicle, the lower or false ribs by their mobility, due to their long cartilages, etc. Hence it is the ribs in the middle of the series, fourth to eighth, that are most often *fractured*. In advanced age the ribs are more liable to fracture, owing to the ossification of the cartilages.

**Fracture** may be due to direct or indirect violence, most often to the former. It may also be due to muscular violence as in coughing, parturition, etc.; but in such cases the ribs are probably pathologically weakened. **Indirect fractures** are due to some excessive pressure, such as being run over. This tends to increase the curve of the ribs, by pressing together their extremities, until they break, theoretically near the middle of their curve but practically in their anterior or posterior thirds. Such violence usually fractures more than one rib and is liable to injure the viscera as well. Theoretically the ends should project outward toward the skin, but practically we find that, owing to the thick periosteum and the intercostal muscles which bind the ribs firmly together, *displacement* of the ends does not occur to any great extent, especially if only one rib is fractured. Hence there is rarely any *deformity* unless several consecutive ribs are fractured. For the same reason, and the intraperiosteal character of many fractures, crepitus and false motion are often not to be elicited. It is probably true however that injury of the lung by the fragments, though it may occur in indirect fracture, is less common than in direct fractures, in which the lesion is beneath the blow and the fragments, if displaced at all, tend to be driven inward, lacerating the pleura and lung. In both forms of fracture the side of the chest injured is strapped to lessen the movements of the ribs on that side.

Notwithstanding the constant movement at the articulations of the ribs they are singularly free from disease, and dislocation is very rare.

**Resection** of one or more ribs is practiced for necrosis, drainage of an empyema or in the Estlander or Schede operation for chronic empyema. In resection the periosteum is incised and separated from the rib, *i. e.*, the rib is resected *subperiosteally*. In this way we avoid injury to the pleura, which is separated from the ribs by the periosteum and the *endo-thoracic fascia* lining the chest cavity. The *intercostal vessels and nerves*, in the grooves behind the lower border of the rib, are also avoided for they lie behind the periosteum. (Fig. 54.) Resection of an inch or so of rib is done to allow more free drainage than is secured in the narrow intercostal spaces. The seventh rib or the rib above or below it is usually selected. As the ribs form a firm arch there is no opportunity for retraction of the thoracic wall to obliterate the cavity of a chronic empyema and the lungs are bound down and can not expand. The Estlander and Schede operations meet this difficulty by resecting several inches of a number of consecutive ribs over the cavity. The arch of the ribs is thus broken and both ends, as well as the intervening soft parts, may sink in and help to close the cavity beneath.

**The intercostal spaces** are narrower behind than in front, in expiration than in inspiration and, in lateral inclination of the thorax, on the side toward which it is inclined than on the opposite side. The third space is the widest and next in order the second, first, fourth, etc. Any of the first five spaces will admit the index finger. The *contents* of the intercostal spaces include the external and internal intercostal muscles, covered externally by a thin fascial layer and internally by the *endothoracic fascia* and separated from one another by a layer of cellular tissue in which the intercostal vessels and nerves lie. (Fig. 54.) Between the *endothoracic fascia* and the pleura is a loose subpleural cellular layer. Pus from disease of the thoracic vertebrae or the posterior part of the ribs may work around in the intercostal spaces and appear even as far forward as the sternum.

**Vessels of the Thoracic Wall.**—The aorta and superior intercostals supply intercostal arteries for each space. Between the vertebrae and the angles of the ribs the intercostal vessels pass more horizontally than the ribs till they reach the cover of the lower border of the ribs near the angles. In crossing this part of the intercostal spaces they give off smaller branches which pass to and along the upper margins of the ribs, and they are exposed to injury by incisions or paracentesis. Similarly in the anterior third of the intercostal spaces, where they anastomose with branches from the internal mammary artery, they abandon the protection of the ribs and are more or less exposed. But here, owing to their small size, their injury is not as serious as posteriorly where a fatal hemorrhage may result. Hence *incision and paracentesis* are to be avoided posteriorly and anteriorly and practiced more at the sides. As the vessels lie much nearer the pleura than the surface they are likely to bleed into the pleural cavity when wounded unless the wound is very freely open superficially. It is remarkable that the intercostal vessels, lying in such close contact with the ribs, are almost never injured in fractures of the ribs. This is explained

PLATE XXIV.

FIG. 54.

Vertical section of the sixth intercostal space at the junction  
of its posterior and middle thirds. (Tillaux.)

by the protection afforded by the periosteum and the fact that the fragments are rarely displaced. Owing to the protection of the ribs, in the greater part of their course, the intercostal arteries are seldom wounded, but if wounded they are difficult to secure without injury to the pleura. Paracentesis may be done with care in any space within the limits of the pleura were fluid can be diagnosed. It is usually performed in the sixth, seventh or eighth spaces and midway between the axillary lines, where the overlying muscles are thin, or near the posterior axillary line, or just outside the angle of the scapula, where the latissimus dorsi must be punctured. Especial care must be taken in the lower spaces, like the ninth in the posterior axillary line, not to puncture the diaphragm. The needle or trochar is entered near the upper border of the rib, to avoid the main intercostal vessels, and in inspiration, for the spaces are then wider. The same rules apply to incisions, which however can be made in the lowest spaces with greater safety than puncture, as they are not made blindly.

The intercostal veins accompany the arteries, lying above them. Those in the upper six or seven spaces anastomose with the branches of the axillary vein. (Braune.) The subcutaneous veins of the thorax form an anastomosis between the axillary and the femoral veins, usually through the superficial epigastric veins (see the veins of abdominal wall).

The internal mammary artery runs a finger's breadth from the sternal margin behind the cartilages and interspaces. It is separated from the pleura in the upper two spaces by the endothoracic fascia, which is here thicker than elsewhere, and in the succeeding four spaces by the triangularis sterni muscle. As it is a vessel of some size serious or fatal hemorrhage may follow its injury, and the bleeding is most likely to occur internally into the pleural cavity. As wounds of this artery are uncommon its ligation is seldom called for but may be done in one of the three or four upper spaces. Below this the spaces are so narrow as to require resection of the cartilages. The third space is preferable as this is wider in front than the fourth and the pleura is protected by the intervention of the triangularis sterni and not merely by the endothoracic fascia, as in the second. On either side of the artery, especially mesially, we may find sternal lymph nodes.

The intercostal nerves (or anterior divisions of the thoracic nerves) lie below the arteries in their course behind the lower border of the ribs, though they are at first above them in the upper four spaces. They supply the costal pleura as well as the skin over the greater part of the abdomino-thoracic region, so that pain over the upper part of the abdomen may be due to pleurisy or to pressure on the nerves by pleural collections of fluid, thoracic tumors, caries of the lower thoracic vertebrae, etc. The lateral cutaneous branches perforate the thoracic wall at the digitations of the serratus magnus and the external abdominal oblique. The lateral cutaneous branch of the second nerve crosses the axilla (Fig. 43) to end in the skin of the inner and back

part of the arm (*intercosto-humeral nerve*) where pain may be felt in pleurisy of the upper part of the pleura or from pressure on the nerve in axillary suppuration or in enlargement of the axillary lymph nodes. The intercostal nerves supply both the intercostal and the abdominal muscles (see also nerves of abdominal muscles). It should be remembered that the skin over the upper part of the thorax is also supplied by the superficial descending branches of the cervical plexus. As the posterior divisions of the thoracic nerves descend a considerable distance before ending in the skin (Griffith), the *line of anaesthesia* in fracture of the thoracic spine and the line of pain and cutaneous eruption in herpes zoster is horizontal and not oblique.

The **superficial lymphatics** (above the level of the umbilicus) enter the axillary nodes. The deeper lymphatics in the intercostal spaces run in two sets, the deeper ones, just beneath the pleura, pass forward to the sternal nodes along the internal mammary artery; the more superficial ones pass backward, through small nodes at the back of the intercostal spaces, and enter the thoracic duct.

### The Breast.

**The Breast** (*mamma*) at birth and up to puberty is alike undeveloped in both sexes. A slight secretion of a colostrum-like fluid, with evidences of inflammation, may sometimes occur in the newborn and in boys at the time of puberty. Very rarely the breast is well developed and functionally active in men.

The *female breast* though it develops much at puberty does not reach its *full functional development* until the end of pregnancy and during lactation. After lactation the breast returns to its former condition until again stimulated by a subsequent pregnancy. After the menopause the breast atrophies and at this time is quite likely to be attacked by cancer.

The *virgin breast* is hemispherical, *extending* between the third and sixth ribs and between the sternal and anterior axillary borders. Its *circumference* is not quite circular but presents three cusps, one toward the sternum and two towards the axillary line, one above and one below. After repeated pregnancies the breast becomes more flabby and pendent, so that its position is not a reliable landmark. In certain *black races*, as in the Basutos, it is flask-shaped and may even be flung over the shoulder or beneath the axilla, so that the infant may suckle on the back.

The breast (Fig. 55) lies upon the pectoralis major muscle, slightly overlapping it onto the scalenus anticus muscle below. The *superficial fascia* of the region splits to enclose and support it, and sends fibrous processes to connect the several lobes together. Fibrous *trabeculae* connect the gland with the overlying skin and more loosely with the underlying pectoral fascia. The enclosing fascia is rich in *fat*, which thus comes to lie in front and behind the gland and between its lobes. Except during lactation, and oftentimes then, the *size* of the mamma is largely due to the relative amount of this fat, which gives the breast,

with its ten to sixteen lobes, its smooth and uniform contour and elastic consistency. Hence the large size of the breast is no indication of good nursing qualities but often the reverse, the fat being developed at the expense of the gland tissue. During lactation and in conditions of emaciation the fat is largely absorbed, so that the gland feels more distinctly lobular. *Posteriorly* the mamma is loosely connected with the pectoral fascia by loose connective tissue which may enclose large lymph

FIG. 55.

Right breast in sagittal section, inner surface of outer segment. (GERRISH, after TESTUT.)

spaces, the so-called submammary bursa. This is one of the sites selected for injection of hot normal saline solution in shock or septicæmia.

Normally the breast should be *movable* in all directions on the pectoral muscle, the failure of such mobility indicates deep extension of the growth in cancer of the breast. This mobility may be tested after the muscle is made firm by its contraction. At the same time the breast moves somewhat with the movement of the muscle, hence the arm should be held at rest in inflammation of the gland.

It is most important to remember that small glandular extensions may pass from the base of the gland to and even through the pectoral fascia so as to lie upon or in the muscle. It follows that every operation of excision of the breast for cancer, to be thorough, should remove this fascia and the surface, if not the entire thickness, of the underlying pectoral muscle. Similarly the fibrous *trabeculae* (*suspensory ligaments of Cooper*), which connect the gland with the skin, may contain true glandular tissue (Stiles), hence no overlying skin should be left in excision for cancer.

The *overlying skin*, except that of the areola, should be freely movable, but in abscess or advanced carcinoma it may become adherent, and in some cases of the latter it is infiltrated with small nodules of carcinoma. In lactation or in cases of carcinoma the large and numerous *subcutaneous veins* are often very plainly visible. The *skin of the areola and nipple* is fatless, pigmented, very thin and sensitive, and adherent to the parts beneath. Besides highly developed papillæ the skin of the nipple contains numerous *sebaceous glands* whose secretion protects the nipple from the saliva of the infant and guards it from fissures. The latter occur most often in the groove between the nipple and the areola where none of these glands open. The tubercles of Montgomery in the skin of the areola, which are enlarged in pregnancy and lactation, represent accessory milk glands rather than sebaceous glands, though *embryologically* the breast represents modified sebaceous glands.

*Beneath the skin* of the nipple and areola are *pale muscle fibers*, both circular and radiating, which act as a *sphincter* on the lacteal ducts traversing the nipple. By their contraction a part of the areola is drawn up into the nipple, thus lengthening and erecting the latter, which is not really an erectile body. The *lacteal ducts*, one for each lobe of the gland, after enlarging into a spindle-shaped ampulla or reservoir beneath the areola, converge to and traverse the nipple to open separately by fine orifices ( $\frac{1}{2}$  mm.) near its tip.

Besides ordinary *ezema* of the nipple the latter may be the seat of a chronic, superficial, reddened, finely granular, raw condition known as *Paget's disease* of the nipple which results in epithelioma of the lacteal ducts. By a contraction of the lacteal ducts, or of new connective tissue about them, in scirrhous cancer, the *nipple* may be retracted so as to present a depression instead of a projection.

**The nipple** averages half an inch in *length*, lies a little below and internal to the center of the gland and points outward. In the virgin it corresponds to the fourth interspace (or fifth rib) four inches from the median line, but its position is very variable after pregnancy or in old age. In some cases it is depressed below the surface so as to prevent lactation. The *consistency* of the breast is *firm* without being hard. It is not entirely uniform in all parts, but if any part is distinctly hard it is pathological.

**Abscess** of the breast is not uncommon during lactation and is usually due to an infection carried by the lymphatics from a fissure or

eczema of the nipple or areola. It may occur in *three situations*, (1) in the fatty connective tissue superficial to the breast, (2) in the breast tissue itself or its interlobular tissue, and (3) in the loose submammary connective tissue. It occurs most often in the breast tissue and one or more lobes or the entire organ may be involved. Incisions to open mammary abscess should *radiate from the nipple* to avoid damage to the lacteal ducts.

The blood supply of the mamma comes mainly from the *long thoracic artery* (external mammary), which follows the outer border of the pectoralis major, also from the second, third, fourth and fifth perforating intercostal branches of the internal mammary artery and in addition from the corresponding aortic intercostals and perhaps from the acromiothoracic. The veins follow the same course. These arteries and veins are divided in excision of the breast.

The lymphatics are of special importance as it is through them that metastatic infection occurs in carcinoma of the breast. The superficial or subcutaneous and the deep or glandular set of lymphatics unite in a plexus beneath the areola. The principal outlet is by two or three large vessels which pass along and beneath the external border of the pectoralis major to the pectoral group of the axillary nodes (see lymphatics of axilla). The *first two nodes* which those vessels enter, and consequently the first to be affected by metastatic growth in cancer of the breast, usually lie on the third rib on the serration of the serratus magnus. From these the infection spreads to other axillary nodes and the subclavian nodes. Hence we see the necessity of *complete removal of the axillary nodes and contents* in any operation for carcinoma. From the inner part of the gland vessels also pass through the intercostal spaces to the sternal nodes, along the internal mammary artery, and thus reach the mediastinal nodes whence indirectly the liver, pleura and lungs may become involved. As the superficial lymphatics of the inner part of the breast may cross the median line and enter the nodes in the opposite axilla, the involvement of the latter is a possibility, and actually occurred in one case reported by v. Volkman.

As the mamma is supplied by the *cutaneous branches of the second, third, fourth and fifth intercostal nerves*, abscess or other painful affections of the breast may cause pain referred to the side or back of the thorax (intercostal trunks), the region over the scapula (posterior divisions of thoracic nerves) or down the arm (intercostohumeral branch of the second intercostal). Pain shooting up the neck is probably along the supraclavicular branch of the cervical plexus which reaches the upper part of the gland and also communicates with the second intercostal. *Sarcoma* of the breast may develop from the connective-tissue stroma of the gland, *carcinoma* from the glandular elements.

**Abnormalities.**—Small *supplementary glands* are often present around or near the mamma and may be the starting point of many tumors. Occasionally *additional mammae or nipples* exist, sometimes in the axilla but more often (90 per cent.) below the regular glands, verging toward the median line so as to follow the course of the inter-

nal mammary and deep epigastric vessels. They may even occur in the groin. The occurrence of these is explained by reversion or *atavism*. *Absence* and *imperfect development* of the breasts are rare and usually associated with absence or arrested development of the sexual organs. The *nipples* on each breast may be double or even triple or again they may be wanting.

### The Diaphragm.

The diaphragm, situated at the junction of the superior third with the inferior two thirds of the trunk, forms the *floor of the thoracic cavity* and the roof of the abdomen. It is not a single but a double or bilateral muscle, with a central tendon. Its muscular fibers, arranged peripherally, may be divided into sternal, costal and lumbar (or vertebral) portions. Between these portions the muscle fibers may be wanting over a greater or less space, so that the serous or subserous layers on either side come together. Thus the muscle fibers are often wanting (*hiatus diaphragmaticus*) between the vertebral part, comprising the crura and the fibers from the arcuate ligaments, and the costal part, favoring the passage of inflammation or pus from a perinephritic abscess into the pleural cavity, or the occurrence of a hernia. Similarly between the sternal portion, from the back of the xiphoid cartilage, and the costal portion on either side are *gaps* devoid of muscle, covered above by pleura on the right side and pericardium on the left. Through these gaps pass the superior epigastric arteries and some hepatic lymphatics, on their way to the mediastinal glands. Also between the two halves of the sternal (xiphoid) insertion is usually a gap through which the cellular tissue of the mediastinum is continuous with the subperitoneal connective tissue, and through this gap inflammation and pus may pass or extend from the mediastinum to the epigastric region or vice versa.

Through some one of the above *gaps* diaphragmatic hernia either *congenital* or *acquired* is most likely to occur. In the former variety one of the gaps, especially the xiphocostal, may be congenitally large or a portion of the diaphragm may be deficient. The *acquired form* is due to a muscular strain or external violence. It may be suddenly acquired, as by a fall or blow, in which case there is likely to be rupture of the peritoneum and hence no sac; or gradually acquired, as by straining, coughing, etc., when a sac is usually present. Almost *any of the abdominal viscera*, but especially the stomach, colon and omentum, *form the contents* of such a hernia in the pleural cavity. The lungs, owing to their elasticity, are never herniated into the abdomen. Many of the acute acquired cases are rapidly fatal and often are not diagnosed ante mortem, but if diagnosed *surgical intervention* offers the only hope.

The fleshy portion of the diaphragm, arising in an oblique line from the base of the xiphoid cartilage to the last rib and the lumbar vertebrae, passes at first vertically upward, connected with the inner surface of the thorax by connective tissue, to the lower limit of the pleura (see p. 215). Thence lined above by pleura it is separated from the

thoracic wall by a cleft-like space lined by pleura (*costophrenic sinus*), into which the lung does not descend in deep inspiration. Thence (*i. e.*, from the level of the lower border of the lung) the diaphragm curves upward and inward, concave inferiorly, into the trefoil central tendon. Hence in the lower part of the bony thorax a wound involves the thoracic wall, diaphragm and peritoneal cavity; at a higher level it involves the thoracic wall, pleural cavity, diaphragm and peritoneal cavity; still higher the lung intervenes in the pleural cavity. Unless the lower part of the pleural cavity is filled with fluid or gas the diaphragm is in close contact with the chest wall below the lower border of the lung, a fact to be remembered in incisions here.

The **level of the diaphragm** varies between ex- and inspiration. The middle portion or *central tendon*, on the central or left leaflet of which rests the heart, stretches from the base of the ensiform process nearly horizontally backward to the vertebrae. This portion moves slightly in respiration (about 1 inch, Sibson), though Hyrtl thought it stationary. The pericardium and heart must necessarily follow its movements, hence its motion is slight. The *dome, or highest point* of the diaphragm, reaches the *level* of the fifth cartilage on the *right side*, or one inch below the nipple, on the *left* the breadth of a cartilage lower, the presence of the liver making the right side higher. In *early life* the diaphragm is higher than given above and it is lower in *old age*. The *height* of the diaphragm is altered by pathological conditions in the thoracic and abdominal cavities. Thus it is *lowered* in pleural or pericardial extravasations and in emphysema, and *raised* when extensive adhesions exist in the pleural cavities with retraction of the lung or when tumors, fluid or meteorism are present in the abdomen.

As to the **three openings** in the diaphragm, the *aortic opening* in front of the twelfth thoracic vertebra, lies in or slightly to the left of the median line. The inner portion of the two crura which arch in front of the aorta to form the aortic orifice is fibrous, so that the contraction of the diaphragm does not cause compression of the aorta. The *oesophageal opening*, above and in front of the aortic opening and to the left of the latter and the median line, is oval and surrounded by fleshy fibers. It lies in front of the ninth thoracic vertebra. Very rarely the *oesophageal opening* is found in the right crus, in the median line, or to the right of it. I have found this condition in one case of gastrotomy, preliminary to a retrograde dilatation of an *œsophageal stricture*, and another similar case has been recently reported.

The *pleura* of both pleural cavities and the *pericardium* are closely connected with the diaphragm, the *peritoneum* more loosely. The under surface of the heart resting on the central tendon of the diaphragm explains the presence of the heart beat in the epigastrium, and its exaggeration in hypertrophy of the right ventricle. The liver, stomach, spleen, pancreas, kidneys and suprarenals are in contact with the under surface of the diaphragm, the lungs and heart with the upper surface.

The diaphragm is supplied by the *phrenic nerves* in paralysis of which respiration is carried on almost entirely by the intercostals and

the epigastrium sinks instead of protruding on inspiration, as the diaphragm no longer pushes the abdominal viscera downward and forward. In *action* the diaphragm increases the vertical diameter of the thorax but as it also raises the lower six ribs it increases the other two diameters in the lower part. When fixed in the position of inspiration by the closure of the glottis, it assists the abdominal muscles in expulsive efforts, defecation, parturition, etc., by pressing down the abdominal viscera and holding them there. The abdominal viscera press the diaphragm upward in the supine position, hence many patients with dyspnoea breathe better in the sitting posture.

### The Pleura.

The pleura of each side is a large serous sac or *lymph space* whose median or mediastinal wall is invaginated at one point (the root of the lungs) by the lung whose outer surface it covers as the visceral or pulmonary pleura. Normally there is no pleural cavity, the opposing

FIG. 56.

Position of the lungs and pleurae with reference to the anterior chest wall. (JOESSEL.)

smooth, inner surfaces of the pleura being in contact with only a slight amount of fluid between to diminish friction. Pathologically the presence of fluid (serum, pus) or air may make a cavity. It is important to know the limits of the pleura both for diagnosis and treatment.

The dome of the pleura is completely occupied by the apex of the lung and, like the latter, is grooved by the subclavian artery antero-internally, hence in ligation of the artery the pleura is in danger of injury. The pleural dome and the apex of the lung extend into the root of the neck 5 cm. (2 in.) above the anterior part of the first rib, but never above its neck, and 1 to 3 cm. above the clavicle in the upright position, but scarcely or not at all above it in the supine position or in forced inspiration, in which positions the clavicle is elevated. Clinically the resonance on percussion of the apex extends higher above the clavicle than its actual level. The dome of the pleura is in relation with the scaleni medius and anticus and the deep layer of the deep cervical fascia. It lies behind the inner end of the clavicle and the sternomastoid muscle and projects into the base of the posterior cervical triangle.

The anterior borders, along which the costal and diaphragmatic portions of the pleura meet in front, extend from the dome downward and inward behind the sternoclavicular joints and the sternum meeting opposite the junction of the manubrium and the body of that bone a little to the left of the middle line. From this point they descend vertically and nearly, or sometimes quite, in contact, to the level of the fourth or fifth cartilage whence they diverge to reach the seventh chondrosternal junction, leaving between them a triangular area of sternum in contact with the pericardium. The left pleura below the fourth cartilage passes along the left border of the sternum, or at most the inner ends of the fourth to the sixth costal cartilages, but does not bend outward, as does the cardiac incisure of the lung, to leave the pericardium bare. Hence under normal conditions the pericardium cannot as a rule be punctured through an interspace without traversing the pleura.

The lower border of the pleura, along which the costal and dia-phragmatic portions meet, reaches the upper border of the seventh cartilage at the side of the sternum, the lower border of the seventh rib in the mammary line, the ninth rib in the axillary line and the twelfth rib or eleventh thoracic spine at the side of the vertebræ. It may extend slightly below the inner end of the twelfth rib, occasionally even to the lower border of the first lumbar transverse process (Pansch), an important point in lumbar incisions to reach the kidney (see p. 282). Although the left pleura may extend somewhat lower than the right, owing to the liver on the right side, the difference in level is so slight that clinically it is not worth considering. The posterior border, extending between the neck of the first and the head of the twelfth rib, is indicated in part by a ridge bounding posteriorly the groove which on the left side is formed by the aorta and on the right side by the azygos major vein.

Along the anterior and inferior borders the lungs do not reach as far as the pleuræ but leave an interval or sinus where two layers of parietal pleura are in contact. The costomediastinal sinus, or that along the anterior border, is filled by lung in inspiration on the right side, but on the left side, opposite the cardiac incisure of the lung, a

wide interval remains in the fullest inspiration, corresponding to the area of cardiac flatness, where the heart is uncovered by lung.

The costophrenic sinus, along the lower border of the pleura, is never filled on the deepest inspiration. The extent of the contact of the costal and phrenic portions of the pleura varies in different parts and on inspiration and expiration, and corresponds to the difference of level of the lower borders of the pleura and lung. In quiet breathing this sinus measures 2 cm. at the sternal and mammary lines, 2.5 cm. near the vertebrae and 6 cm. in the axillary line (Luschka).

FIG. 57.

Position of the lungs and pleurae with reference to the posterior chest wall. (JOESSEL.)

Pathological fluids first collect here and can here be first diagnosticated. The presence of the sinus explains the fact that a *wound* may penetrate the pleura and the diaphragm, and then enter the peritoneal cavity or the liver, without involving the lung. Unless we are sure that this sinus is full of fluid it is not safe to *puncture* the pleural cavity below the lower limit of the lung, though an *incision* may be carefully made at the lower limit of the pleura. The *lower limit* of the sinus is still quite a distance above the lower attachment of the diaphragm and the costal margin (about  $2\frac{1}{2}$  inches from the latter). The thin diaphragm alone separates the lower end of the pleurae from the kidneys. The pleura is said to descend lower in the child. In children also the thymus separates the anterior borders of the pleurae more widely than

in the adult. The thick *costal pleura* is so connected with the endothoracic fascia by loose connective tissue that it is easily stripped up, while the *diaphragmatic pleura* is closely adherent.

Above the level of the root of the lung the *mediastinal pleura* stretches evenly between the sternum and the vertebræ, covering the vessels of the mediastinum. Along the root of the lung the parietal (mediastinal) is continuous with the visceral pleura. Opposite and below the root of the lung the mediastinal pleura covers and is closely attached to the outer surface of the pericardium, with the phrenic nerves between, hence the latter may be affected by inflammation of either membrane. The attachment to pericardium is more extensive on the left side, as the heart projects more into the left half of the thorax. Behind the pericardium the mediastinal pleura on either side forms a triangular fold connected with the posterior border of the lungs from the hilum down, 6–8 cm. in length, the *ligamentum latum pulmonis*. Its base stretches over the diaphragm, when the lung is pulled laterally, and is free. In removing the lungs the broad ligaments as well as the roots must be divided.

The thin *visceral or pulmonary layer* of the pleura, besides covering and being closely adherent to the surface of the lungs, dips down into the bottom of the fissures, both surfaces of which it lines.

In *pleurisy*, or inflammation of the pleura, the opposing surfaces, pulmonary and parietal, are congested and then thickened and roughened by cell proliferation. The rubbing together during inspiration of these roughened areas causes the friction sounds and pain, hence the chest is strapped in pleurisy to prevent the movement of the lungs. As the intercostal nerves supply the intercostal and other respiratory muscles as well as the costal pleura, the patient with pleurisy neither will nor can draw a deep breath on account of pain. *Adhesions* may form between opposed roughened areas of the pleura. When *fluid* is extravasated this first accumulates in the costophrenic sinus, or posteriorly in the supine position. If the fluid is excessive the lungs are pressed backward and inward toward the hilum and the costovertebral groove. The occasional rapid absorption of large quantities of pleuritic effusion is explained by the fact that the pleura is a large lymph space. In the cases of "*pleurisy with effusion*" running a longer course the hyperplastic thickening may be very marked and the adhesions, when the fluid is removed, may be very extensive.

In *wounds* penetrating the pleura air may enter the pleural cavity causing *pneumothorax*. If the opening is free the elasticity of the lungs causes them to collapse and retract toward the hilum; if the opening is not free the respiratory movements may force the air into the subcutaneous tissues, producing *subcutaneous emphysema*. Owing to the close contact of the visceral and parietal layers of the pleura the latter can scarcely be wounded, except in the sinuses, without wound of the former. Emphysema may also be caused by a ruptured vomica or by a wound of the lung such as is sometimes seen in fractured ribs, the air coming from the opened bronchi, etc. (see p. 205). Some non-

penetrating wounds may also cause such an emphysema, the air being drawn in during one movement of respiration and forced into the tissues during another, the valvular nature of the wound preventing its escape. **Hernia of the lung**, through a wound of the thoracic wall, can only occur when the lung fails to collapse, and this implies that the glottis was closed at the time of injury, or that extensive adhesions bound the lung to the chest wall. In the latter case the adhesions would prevent hernia. In *hemothorax*, or blood in the pleural cavity, there is usually a wound or lesion of the lung, but the blood can come in greater or less part from the parietal wound.

### The Lungs.

The two pyramidal-shaped lungs occupy about four fifths of the thoracic cavity proper.

**Position.**—Contained in the two pleural sacs their **apices** correspond in position to the domes of the pleura which they completely fill. From the apices of the lungs the **anterior borders** (Figs. 56 and 57), which become thin and sharp about 4 cm. below the apices, descend convergingly behind the sternoclavicular joints and nearly meet behind the sternum, opposite the second cartilages. Thence they descend vertically to the level of the fourth cartilages. In infants the thymus separates the anterior borders more widely, the right lung barely reaching the median line while the left only reaches the left sternal border (Symington). From the level of the fourth cartilages the right lung bends slightly outward to reach the upper border of the sixth chondro-sternal junction, while the left lung curves sharply outward, with an external convexity, across the fourth space and the fifth cartilage and thence back to the inner end of the sixth left cartilage. In expiration this "*cardiac incisure*" may reach to, or nearly to, the apex of the heart, which is covered by the lingula. It forms the left boundary of the area of cardiac flatness and the right border of the lingula of the left upper lobe.

The **level of the lower border** (Figs. 56 and 57) is especially important for the diagnosis of certain pulmonary conditions. In quiet breathing the lower border is at the upper border of the sixth costal cartilage in the sternal line, the upper border of the seventh rib in the mammary line, the lower border of the seventh rib in the axillary line, the ninth rib in the scapular line, the upper border of the eleventh rib or the tenth space at the vertebræ. It will thus be seen that the level of the lung at any line except the sternal is the same as the level of the pleura at the line next anteriorly (see p. 215). The left lung is said to be longer and extend lower than the right lung but the difference is so slight, if it exists, that it is not worth considering from a practical clinical standpoint. In deep inspiration the lower border descends about an inch and a half (Godlee), in emphysema it is permanently lower, in the aged it is one half to one intercostal space lower and in children the same distance higher than in the adult. The **posterior border**, extending from the neck of the first rib to the eleventh rib, is

usually taken to be the rounded part occupying the costovertebral groove but, as stated above (see p. 215), it is better to consider it the ridge bounding the back of the groove for the aorta on the left and the azygos major vein on the right. To this border is attached the ligamentum latum, below the hilum. Normally the surface of the lung is everywhere in contact with the parietal pleura, which thus supports it, and it is further held in position by its attachment to the mediastinum by means of the root of the lung and the ligamentum latum.

**Relations.**—The concave base of the lung resting on the *diaphragm* is only separated by the latter and its serous coverings from the *abdominal viscera* in contact with it, liver, stomach, spleen, kidneys, suprarenals. Inflammation, abscess and tumors of these organs, after penetrating the diaphragm, may involve the pleuræ and lungs and vice versa. On *percussion* we distinguish the lower border of the lung on the right side by the contrast between the pulmonary resonance and the liver dullness below it, and on the left side by the less marked contrast between the tympanitic resonance of the stomach and the pulmonary resonance. Internally the *heart* and many of the *great vessels* of the mediastinum are in relation with the lungs. The greater projection of the heart on the inner aspect of the left lung inferiorly makes the left lung, and especially its base, narrower than the right and accordingly its bulk and weight are less. The left lung averages twenty ounces, the right lung twenty-two ounces in *weight*, but the weight may be greatly increased by disease. The *subclavian artery* grooves the fore part of the upper end of the *apex* in a transverse direction.

The fissures extend deeply toward the hilum. The *fissure* (Figs. 56 and 57) which separates the upper from the lower lobe commences on both sides at the posterior border three inches below the apex, on a level with the third thoracic spine or the inner end of the spine of the scapula. Thence, sweeping around the convex surface of the lung, it meets the lower border in the mammary line on the right side, and at the outer end of the sixth cartilage on the left side. On the right side this fissure crosses the convex surface somewhat lower than on the left and from about its middle, or where it crosses the posterior axillary line, a *second fissure* (Fig. 56) passes nearly horizontally forward to the fourth right chondrosternal junction, separating a *middle lobe* from the upper lobe.

*Posteriorly*, practically all the lung above the level of the inner end of the spine of the scapula is upper lobe, all below is lower lobe. *Laterally*, in the *axillary line*, all the lung above the fourth rib on both sides belongs to the upper lobe, while on the left side all below belongs to the lower lobe, and on the right side from the fourth to the sixth rib belongs to the middle lobe, all below the sixth rib to the lower lobe.

*Anteriorly*, in the *mammary line*, on the left side all the lung above the middle of the fifth space belongs to the upper lobe, all below to the lower lobe; on the right side all above the fourth rib belongs to

the upper, all below to the middle lobe. We thus see that the lower lobe is not only below but behind the upper lobe. These points are of practical importance in the *physical examination* of the lungs, especially when pneumonia or tuberculosis are suspected, for in the former the lower lobe and in the latter the upper lobe are most often involved.

The **apex** of the lung is a favorite site for *pleural adhesions* and for *tubercular lesions*. The frequency of adhesions may be accounted for by the fact that the apex at all times fills the dome of the pleura and, being a narrow portion of lung tissue, its motion is slight; and by the fact that the apex is frequently the seat of lesions which may lead to a pleurisy. In proportion to its bulk the apex probably expands as much as any other part of the lung, so that the prevalence of tubercular lesions here is not to be accounted for by the stagnation of the air current in this part (see p. 221).

The concave *median surface* presents the oval fissure or **hilum** where the structures contained in the **root of the lungs** emerge or enter. The upper end of the hilum is at the junction of the upper and middle thirds of this surface, opposite the disc between the fifth and sixth thoracic vertebrae, and at the junction of the anterior three fourths with the posterior fourth of this surface. Hence the root of the lung is more accessible from behind. The neighborhood of the root of the lung, on account of the large vessels here, must be avoided in **puncturing the lung** with a needle for diagnosis. This may be safely done over the greater part of the anterior surface to the depth of  $1\frac{1}{2}$  inches in a backward and outward direction. In puncturing the apical part from in front, through the first or second spaces, remember that the internal mammary artery is a finger's breadth from the sternum and the axillary vein is  $3\frac{1}{2}$  inches from the middle line in the first space and  $4\frac{3}{5}$  inches in the second space.

The **color** of the lungs changes from a reddish brown in the *foetus* to a pinkish white *at birth*, owing to their insufflation with air. In the *adult* they are slate-colored, with a darker mottling of certain lobules, which increases with age, is very marked in coal miners, etc., and is due to the deposit in the interlobular tissue of carbonaceous particles absorbed by the lymphatics. The **specific gravity** of the lungs is normally lighter than water so that they float, but in certain diseased conditions (pneumonia, etc.) and in the *foetus* that has never breathed they sink. This fact is useful *medicolegally* to determine whether an infant was still-born or born alive. If the child has breathed the **weight** of the lungs also increases by one third (on account of the access of blood), the **size** increases and the **consistency** is altered by *aération*.

While the **capacity** of the lungs after the deepest inspiration averages 5,000 cm., 1,500 cm. of this (*residual air*) can not be expelled by the fullest expiration. The total capacity minus the residual air, or 3,500 cm., is the **vital capacity** of the lungs and is liable to be affected by various diseases of the lungs. In quiet breathing 1,500 cm. of "reserve air" remain after expiration in addition to the residual air,

and in inspiration only 500 cm. are breathed in, leaving 1,500 cm. of *complemental air* to be inspired by a forced inspiration.

**Vessels.**—The *bronchial vessels* supply the mechanism of the lung, or the lung stroma. They anastomose to some extent with the pulmonary vessels and so may be of service in stenosis or closure of the pulmonary artery, which is extremely rare. The **pulmonary artery** in its course to and through the lung is curved with an *upward convexity*. From the convex surface the first branch given off passes to the upper lobe and apex. Solid particles in the current which have a specific gravity greater than the blood tend to hug the upper wall and to pass into the first branch given off from this part. Thus they pass into the upper lobe and apex. This is the probable explanation of the more frequent occurrence of tuberculosis in the apex, especially as the tubercles are first observed in the walls of the smaller arteries at their points of bifurcation.

When a branch of the pulmonary artery is plugged by an embolus the circulation is stopped in the area supplied by it. This is called an *infarct* and is wedge-shaped with the apex at the plug and the base on the surface of the lung, for such is the shape of the area supplied by the vessel, whose circulation is terminal. If such an embolus is infective an abscess may result. Only in the lung can the embolus come from a systemic vein, so that the lung is a frequent seat of pyæmic infarcts and abscesses.

The **lymph vessels** of the lung empty into four or six nodes in the root of the lung which are accessory to the bronchial nodes. The root nodes are black from the pigment absorbed in the lungs. They are often diseased, and thus menace the neighboring parts.

In the **bronchi** the *muscular tissue* is arranged circularly and, by its reflex irritation from the vagus, as in indigestion, or by direct irritation in uric acid or uræmic conditions, it may contract suddenly and give rise to an attack of *spasmodic asthma*. In chronic *interstitial pneumonia* the pull of the contracting new tissues draws apart the walls of the bronchi, as these offer less resistance than the retraction of the chest wall. Large bronchial cavities (*bronchiectasis*) are thus formed, in which the fluid collecting is liable to decompose and give rise to fetid breath and expectoration.

The **alveoli** of adjacent infundibula were formerly thought to be independent, but by corrosion preparations anastomoses are found between them and even between those in adjacent lobules. In *vesicular emphysema* some air cells are distended, others are blended with one or more adjacent cells, and thus the oxygenating capillary area of the lung is diminished. In *interlobular emphysema* the air cells burst and allow the air to escape into the pulmonary connective tissue.

The **elasticity** of the lung is one of its striking and important features. It assists expiration, is one of the factors producing pigeon breast in the rachitic, explains the fact that in rupture or wound of the diaphragm the lung is never herniated into the abdomen, and it maintains the vault of the diaphragm. If the lung is wounded within

the limits of a pleural adhesion subcutaneous emphysema may be produced but not pneumo- or haemothorax. When the *pleural cavity* is opened through the thoracic wall, or through the lung, the atmospheric pressure within and without the lung is equalized, and hence it retracts, owing to its elasticity. In such cases we have a sero-sanguinous extravasation and air in the pleura and if the chest wall is injured, as by a fractured rib, subcutaneous emphysema is likely to occur. The gravity of *wounds of the lung* depends largely upon the hemorrhage, hence they are more serious on the internal surface near the large vessels. It is remarkable that the air in pneumothorax seldom contains germs, or at least in sufficient number to infect the extravasation of blood. Wounds of the lung cicatrize rapidly and the air in the pleural cavity is rapidly absorbed. Blood expectorated from the lungs is necessarily coughed up and mixed with air, hence it is frothy and bright red. It is also alkaline, while that retched up from the stomach is acid and dark.

**The Roots of the Lungs** (Fig. 58) contain from before backwards pulmonary vein, artery and bronchus, and from above downward artery, bronchus and vein. On the right side however there is an eparterial bronchus above the artery. In addition the roots contain bronchial arteries and veins, lymphatics and four to six nodes, pulmonary plexuses (anterior and posterior) and nerves, and connective tissue, the whole surrounded by the pleura reflected from the mediastinal to the visceral layers, except below whence the ligamentum latum pulmonis stretches downward. It will thus be seen that the *bronchus lies* posteriorly and between the other parts and when an object is impacted in the main bronchi or their primary divisions they may best be *reached from behind* by making a flap opening into the thorax at the side of the vertebrae at the level of the fourth to the seventh ribs. In such cases the *relations* of the roots of the lungs are important. On the right side the azygos major vein is behind and arches above it, to open into the superior cava; while on the left side the arch of the aorta is above and the descending aorta and oesophagus behind it. On both sides the pneumogastric nerve and the larger or posterior pulmonary plexus are behind, and the phrenic nerve and the smaller or anterior plexus in front. Hence the left side is more covered by important relations and is more difficult to reach, but according to some the pleura is retracted with more difficulty on the right side so that the latter is harder to reach.) The root of the lung measures 3 cm. vertically and 2 cm. antero-posteriorly, the right root is larger, the left longer.

### The Thoracic Portion of the Trachea.

This extends from the episternal notch, at the level of the disc between the second and third thoracic vertebrae, to its bifurcation, opposite the fourth or fifth thoracic vertebra, and includes about half the length of the tube, or  $2\frac{1}{4}$  inches. It *lies* in the superior mediastinum between the two pleural sacs and the vagus nerves, in front of the oesophagus, and behind the remains of the thymus gland, the left

PLATE XXV.

FIG. 58.

Thoracic contents seen from behind. (Joessel.)

innominate vein, the innominate and left carotid arteries and the transverse arch of the aorta. It *bifurcates* behind the lower border of the aortic arch at about the level of the junction of the first and second pieces of sternum, or of the inner end of the spine of the scapula. Hence abnormal sounds produced at the tracheal bifurcation, or in the primary bronchi, can best be heard between the shoulders at this level. Surrounding the bifurcation of the trachea are twenty to thirty *bronchial lymph nodes*, which are frequently diseased and may press upon and narrow the trachea or adhere to and ulcerate through it. Stenosis of the trachea from syphilitic lesions or from aneurisms of the aorta or the great vessels are apt to occur at the upper or lower ends of the trachea.

Of the two *bronchi the right* is the larger, so that the dividing ridge between the two bronchi lies to the left of the median line and the trachea seems to lead more directly into the right bronchus. Hence, and by reason of the greater intake of air, foreign bodies are more likely to pass into the right bronchus and, as we have already seen, this is the side most safely exposed from behind. Foreign bodies at or a little below the bifurcation of the trachea may often be removed by forceps introduced through a low tracheotomy opening, or they may be spontaneously expelled by a fit of coughing through the open tracheal wound or through the larynx. In other cases they have ulcerated through the bronchus and been discharged through an abscess at the back, adhesions having shut off the pleura; Mr. Godlee records a case where a head of rye so escaped.

The *course* of the bronchi is toward the hind part of the lower surface of the lung (*i. e.*, behind the axis of the lung). Hence, of the ventral and dorsal branches given off by the bronchi the former are much the larger. The *right stem bronchus* is slightly curved inward and is more vertical than the left, which is displaced laterally by the heart and takes an S-shaped curve, being first displaced inward and downward by the aortic arch. The *relation* of the latter explains the pressure of *aneurisms* on this part of the left bronchus. The right undivided bronchus averages one inch in *length*, the left two inches. The latter enters its lung an inch lower than the right, opposite the sixth thoracic vertebra.

### The Pericardium.

The pericardium, like the pleura, is a closed invaginated sac. But it is more complicated than the pleura, for instead of one there are seven reflections which connect the parietal and visceral layers and form more or less complete sheaths around the great vessels at the base of the heart. Between these sheaths there are a number of pouches or sinuses, of which the largest is the great or *transverse sinus*, between the auricles behind and the tubular sheath of the aorta and pulmonary artery in front. An encapsulated effusion may occur in this sinus, the pressure of which is exerted principally upon the thin-walled *vena cava superior*. Sinuses like those of the pleura exist only

to a slight extent at the reflection of the pericardium from the diaphragm. The tubular pericardial sheath common to the aorta and pulmonary artery is the only complete one among the seven. It covers the proximal  $1\frac{1}{2}$  inches of these vessels, which is therefore within the pericardial sac. The *parietal layer* is reinforced externally by a *fibrous layer* which blends with the outer coat of the great vessels beyond their serous investments and becomes continuous above with the deep cervical fascia.

The elasticity of the parietal pericardium is an important factor. It allows it to be *stretched* to double its size, so as to contain twelve to eighteen ounces in case of acute *pericardial effusion*, or even up to three pints in chronic cases. It is only when the pericardium is greatly distended that the pressure affects the heart and may cause a fatal result. As the *shape* of the pericardium is cone- or pear-shaped, with the base below on the diaphragm and the apex above, this is the shape of pericardial effusions, while in cardiac hypertrophy or dilatation the long diameter is directed transversely. In pericardial effusion the *dullness* reaches beyond the apex beat or, if the effusion is extensive, the apex beat may not be perceptible. When the *sac is but partly full* the fluid, and with it the area of dullness, may shift its position with that of the body and, as it presses upon the bronchi in the reclining position, the patient may breathe more easily in the upright posture. By *excessive pericardial effusion* the lungs are pushed aside laterally, increasing the area of heart dullness, the diaphragm, liver and stomach are displaced downward and the lower two thirds of the sternum and the corresponding left cartilages and spaces are bulged forward.

**Paracentesis** of the pericardium is usually *done* in the fifth left space one inch from the sternum. If a point nearer the sternum is taken there is danger of wounding the internal mammary artery, though if an incision is used and not a puncture we may go close to the sternum. Unless the pleura has been pushed aside by the effusion the trocar will puncture two layers of it one inch from the sternum. The puncture may also be made in the sixth left space with less danger of wounding the heart. Some advise puncturing on the right side of the sternum in the fourth or fifth space, where the distended pericardium also bulges, on the supposition that there is less danger of puncturing the heart itself.

Normally the pericardium is in direct *relation* with the anterior parietes (sternum) only (1) over a small area at its upper end where it is reflected onto the aorta and (2) over a triangular area at the lower end of the sternum where the pleuræ diverge and where, by a trephine opening, the pericardium, uncovered by pleura, may be reached. No true ligaments, only loose connective tissue, bind the pericardium to the back of the sternum. Whereas in front and laterally the pericardium is largely covered by pleura, the phrenic nerves intervening laterally, *posteriorly* it forms the anterior boundary of the posterior mediastinum and is in direct relation with the thoracic aorta, azygos

veins, thoracic duct, and oesophagus, on which pericardial effusion may press, especially in the supine position.

### Heart.

On opening the pericardium in front we see the anterior or **sternocostal surface** of the heart comprising a part of the two ventricles, the right auricle and its appendage and the tip of the left auricular appendage. Of these parts the *right ventricle* presents the greater area, hence it is most often *wounded* in wounds of the heart. The **under surface** rests on the diaphragm and looks also somewhat backward. As the **right ventricle** is one third the thickness of the left we can tell the two apart by the feeling. For the same reason the inferior border, formed of the right ventricle, is thin (*margo acutus*), the left border is thick (*margo obtusus*), so that it may be considered a surface rather than a border. The **left ventricle** is thinnest at the apex and thickest at the junction of its upper and middle thirds. The anterior and posterior *interventricular grooves* meet and are continuous to the right of the apex, and lie near the left and inferior borders respectively.

The heart *lies* obliquely behind the lower two thirds of the sternum, from the upper border of the third costal cartilages to the sternoxiphoid junction. In *front* it is *overlapped* by the pleurae, except behind the lower end of the sternum as described above (p. 215), and by the thin margins of the lungs, except for the area between the pleurae and that of the cardiac incisure, which corresponds to the **area of cardiac flatness**. The latter corresponds to a *triangular area* bounded below by the lower border of the heart, on the right by the left sternal margin up to the upper border of the fourth cartilage, and on the left by a line curved outward from the latter point to the lower border near the apex. A *circle* two inches in diameter, with its center midway between the nipple and the sternoxiphoid junction, would also approximately represent this area.

The anterior or sternocostal surface is the only one accessible to clinical investigation by percussion, etc. Besides the **area of cardiac flatness** we have the **area of cardiac dullness** which corresponds to that part of the anterior surface overlapped by lung and sternum. Owing to the modification of the percussion note by the sternum and the margin of the right lung the *right border* of the heart cannot be definitely determined. As the heart dullness merges into that of the liver below, the *lower border* cannot be determined by percussion, but may be constructed by continuing the lower border of the right lung through the sternoxiphoid junction to the apex of the heart. The *left border* alone is tolerably accessible to percussion and by this we determine changes in the size and position of the heart.

*Laterally* the heart is in contact with the lungs, separated by the pericardium, pleurae and phrenic nerves. It encroaches more on the left side of the chest and the left lung, so that two thirds of the heart are on this side. Only the right auricle and a small part of the left auricle and right ventricle are on the right side of a median vertical

plane. The auricles lie above, behind and to the right of the mass of the ventricles and correspond to the sixth, seventh and eighth thoracic vertebrae. But between the heart and the thoracic spine lies the posterior mediastinum, containing the oesophagus, thoracic duct, aorta and azygos veins.

The **apex**, belonging solely to the left ventricle, is directed downward, forward and to the left and strikes the chest wall in systole in the fifth space  $3\frac{1}{4}$  inches from the median line, or two inches below and one inch internal to the nipple. The *apex beat* may be likened to the recoil of a gun.

**Topography.**—The heart, as projected onto the chest wall, may be mapped out as a *triangular figure*, whose upper truncated angle represents the **base** of the heart, from which the great vessels are given off. The latter is represented by a line across the sternum at the level of the third cartilages, somewhat higher on the left than on the right, and projecting one half inch to the right and nearly one inch to the left of the sternum. The **lower border**, margo acutus, formed by the right ventricle, is drawn from the apex to the junction of the sixth (or seventh) right costal cartilage with the sternum, crossing the sternum near the costoxiphoid junction. This line is nearly horizontal behind the sternum, slightly convex downward to the left of it. The **left border**, margo obtusus, formed by the left ventricle, and the **right border**, formed by the right auricle, are completed by lines convex laterally which connect the left and right ends of these two lines, representing the base and the lower border. The right border projects one to two fingers' breadths from the right sternal margin or one and one half inches from the middle of the sternum.

The **auriculoventricular groove** runs from the third left to the sixth (or seventh) right chondrosternal junction. The **pulmonary orifice** is the most superficial. It lies behind the sternal end of the left third costal cartilage, but the sound of the closure of the valve is transmitted upward with the blood stream and is heard most plainly in the second left space, close to the sternum. The **aortic orifice** is a little below and to the right of the latter, behind the left half of the sternum, opposite the third space. The **mitral orifice** is just to the left of and behind the latter, behind the left border of the sternum and opposite the third space or the fourth cartilage. Notwithstanding the close proximity of these two most important valves of the left heart, there is clinically no difficulty in distinguishing their respective *sounds*, for they are transmitted in the line of the blood stream, so that the sound of the mitral closure is best heard near the apex of the heart, that of the aortic at the sternal end of the second right intercostal space. The points of greatest intensity of the valvular sounds are much more superficial than the valves themselves, especially the mitral valve, which lies furthest posteriorly, behind and a little to the left of the aortic valve. The **tricuspid valve** lies behind the middle of the sternum about the level of the fourth space.

**Displacements of the Heart.**—The *position* of the heart *varies* slightly with its systole and diastole and with the position of the body.

PLATE XXVI.

FIG. 59.

Relation of heart and great vessels to the anterior  
chest wall. (Joessel.)

In *children* the apex is higher, in *the aged* lower than the position given above, the difference between the two amounting to a full intercostal space. The heart is *elevated* in case of ascites, tympanites or tumors of the abdomen which raise the diaphragm, and *depressed* in case of effusion into the pleural cavity, emphysema, large aortic aneurism and mediastinal tumors. If the effusion is on one side only, the heart is *displaced to the opposite side*. Effusions on the left side especially may displace the heart to such an extent as to disturb the circulation and to displace the apex to or beyond the right margin of the sternum. The heart may also be *pulled* to either side by a contracting lung or pleural adhesion. The *descent* of the heart in *inspiration* (about one inch) is not as great as it is made to appear by the elevation of the ribs in front of it. In cases of *transposition of the viscera* the apex beat is found on the right side, and the position of the heart is correspondingly altered. The heart's position is affected by its *enlargement*. This is usually at first in the nature of a dilatation, and then the walls begin to thicken or hypertrophy to compensate for the dilatation. Hence an aortic obstruction, that may for instance be the cause of the dilatation, may be of comparatively little importance if there is compensatory hypertrophy of the left ventricle. The ill effects on the heart in valvular heart disease always extend in the opposite direction to that of the blood stream.

The heart is *supplied* by the *right and left coronary arteries*, the first branches of the aorta, given off from the anterior and left posterior sinuses of Valsalva respectively. They *run* in the auriculoventricular and interventricular grooves and are exposed to injury in wounds of the heart. *Atheroma* of these arteries causes a poor blood supply of the heart, which may result in fatty or fibroid degeneration of the heart muscle, or in angina pectoris. An *embolus* in one of them may cause sudden death from paralysis of the heart muscle.

The *size* of the heart is roughly speaking that of the closed fist, the *weight* varies greatly, averaging 266 to 292 grams. The size and weight of the heart increase up to advanced life and are one sixth less in the female. A physiological hypertrophy, especially of the left ventricle, occurs in pregnancy.

**Wounds** of the heart most often involve the anterior surface, and hence concern the right auricle and ventricle and the left coronary artery and its accompanying vein, in the anterior interventricular groove. Wounds in the third, fourth and fifth spaces close to the right of the sternum are liable to injure the *right auricle*, those in the same spaces to the left of the sternum the *right ventricle*. Wounds of the auricles are more serious and more rapidly fatal than those of the ventricles owing to the thicker walls of the latter and their capacity to contract and prevent the escape of blood. For a similar reason wounds of the right ventricle are more serious than those of the left. Owing to the position of the pleura and its relation to the pericardium, a wound of the normal heart, unless it penetrates the sternum at certain points, must also pierce the pleura, hence blood is apt to be found in

the left (more rarely in the right) pleural cavity. Wounds of the normal heart, except over the area of cardiac flatness, involve also the anterior margin of the lung, hence air may escape into the pericardial as well as into the pleural cavity. Wounds of the heart are not as instantly fatal as commonly supposed. If death occurs at once it is usually due to interference with the heart's action by the presence of blood which has escaped into the pericardium, and not to the effect of the injury on the cardiac nerve centers. Patients with apparently fatal cardiac injuries have lived for some time and others have survived to die of other causes. In a few cases the foreign body causing the injury has been found on post-mortem encapsulated within the heart muscle. Punctured wounds of the ventricle, especially of the left ventricle, may be recovered from. Needles have not infrequently been found imbedded in the heart muscle, having often worked their way there from a nearby situation. *Operations* for cardiac injuries appear to afford a better prognosis than if no operation is done. The *superior vena cava* may be wounded by a stab wound in the first or second right interspace close to the sternum.

### The Aorta.

The first or *ascending portion* of the aorta extends upward, forward and to the right in the axis of the heart. It lies behind the sternum and passes from the aortic orifice, behind the left half of that bone opposite the third space, to the upper border of the right second chondrosternal junction. It reaches to within about 1 cm. of the root of the innominate artery and lies *within the pericardial sac*, covered by the sheath of the serous pericardium common to it and the pulmonary artery. Hence an *aneurism* of this part, before it attains a large size, very commonly bursts into the pericardium, causing sudden death.

The relations of the aorta are of importance in connection with the pressure symptoms of aneurism of its different parts. **Aneurism**, so common in the aorta when its walls are affected by disease, is most likely to involve the ascending part for this is not strengthened, like the arch, by the fibrous layer of the pericardium blending with it. Moreover it is the first part to receive the impulse of the cardiac systole. This impulse is felt especially along its right side where there is a normal bulging of the wall, the *great sinus* of the aorta, from which the current is reflected as it were toward the left into the arch. **Aneurism of the ascending portion** usually bulges to the right and forward. Hence it presses on the superior cava *on the right*, causing congestion of the head, upper extremities and chest wall, and on the sternum *in front* from which it is normally separated by the overlapping right lung and the remains of the thymus gland. The *pulsating tumor* first appears in the second right space but, after erosion of the sternum, this and the upper right cartilages may bulge forward. If the tumor is directed backward it may press upon the right pulmonary artery, which lies behind it, or on the right bronchus behind the artery, caus-

ing a deficient blood and air supply to the right lung and consequent dyspnoea. Again the aneurism may start from one of the *sinuses of Valsalva*, usually the right or anterior one, as the regurgitation of blood after systole occurs particularly here. Such a tumor, usually sacculated, projects chiefly forward and to the right, pressing on the pulmonary artery in front and the right auricle and superior vena cava on the right. The *great sinus* of the ascending aorta projects a slight and varying degree to the right of the sternum, depending partly on the breadth of the sternum, and might be *wounded* in the second right space.

**The arch of the aorta** is badly named the transverse portion of the arch, for its *principal direction* is backward, from about one fourth inch behind the sternum, at the second right chondrosternal junction, to the left side of the body of the fourth thoracic vertebra. Its *transverse course* corresponds only to about the width of the sternum. The downwardly directed concavity or *lower border* corresponds to the junction of the manubrium and body of the sternum. It is also concave to the right and posteriorly. Its convexity or *upper border* corresponds to the level of the third thoracic spine, the middle of the first costal cartilages, the middle of the manubrium or a point about one inch below the episternal notch. In feeble and small-chested persons it may reach nearly to the top of the sternum or in big-chested men it may occasionally lie  $1\frac{1}{2}$  to  $2\frac{1}{2}$  inches below it. It is *covered in front* by the margins of the right and left pleurae and lungs and, between their diverging margins, by the remains of the thymus gland. Toward the left side the left vagus and phrenic nerves cross in front of it. The *left recurrent laryngeal nerve* arches beneath and then behind it, just to the left of the remains of the ductus arteriosus, which connects the arch inferiorly with the angle of bifurcation of the pulmonary artery, or the root of its left branch. The *root of the left lung*, including the left bronchus, pulmonary artery, etc., lies *below it*. Behind it is the lower end of the trachea, just above or at its bifurcation, the oesophagus, thoracic duct, and the left recurrent laryngeal nerve. Its *upper border* is overlapped by the left innominate vein, which covers the roots of its three branches which are given off above, from its convexity.

A consideration of these *relations* will indicate the *pressure symptoms* of an aneurism, which depend upon its position and the direction of its extension. The most common *situation* is on the *posterior or right aspect*, where it may *press upon the trachea*, causing dyspnoea, cough and harsh breathing, and on the *left recurrent laryngeal nerve* paralyzing the left vocal cord, altering the voice and so simulating laryngitis that tracheotomy has sometimes been done. Owing to its pressing more heavily upon the trachea in the reclining position the patient may be unable to lie down with comfort. Extending further backward it may press upon the *oesophagus*, causing dysphagia and simulating oesophageal stricture, or upon the *thoracic duct*, causing inanition. *Extension forward* would involve the sternum and give rise to a pulsating bulging tumor, or press upon the left vagus or phrenic nerves. In case of *exten-*

sion downward the pressure may impede the circulation through the pulmonary artery, and especially its left branch, causing dyspnoea or even cyanosis from the scanty oxidization of the blood. It may obstruct the left bronchus, causing cough, dyspnoea and left-sided harsh and diminished breathing, or finally, it may affect the left recurrent laryngeal nerve. *Upward extension* of the tumor causes pressure on the *left innominate vein*, resulting in serious congestion of the left side of the head and neck and the left upper extremity, or upon one or more of the *primary branches* of the aorta, compressing or even obliterating them, and causing inequality of the carotid or radial pulses on the two sides.

The tumor may extend up into the root of the neck, resembling aneurism of the innominate, left carotid or subclavian arteries, and cause difficulty in diagnosis. Aneurisms of the ascending aorta and the arch of the aorta are liable to lower the heart and to disturb the heart's action by pressure upon the cardiac plexuses. They may *burst* into any of the cavities or hollow tubes with which they are in contact, causing a sudden fatal hemorrhage. The *percussion note* may be dull over a considerable area, owing to displacement of the lungs laterally.

Most descriptive text-books speak of a short third or descending portion of the arch, but there is no sufficient reason for separating this from the *descending thoracic aorta*, which extends from the fourth thoracic vertebra to the aortic orifice of the diaphragm, opposite the twelfth vertebra and slightly to the left of the median line (Joessel). Superiorly it *lies* to the left, inferiorly in front of the *thoracic spine*, superiorly to the left and inferiorly behind and to the right of the *œsophagus*, and superiorly to the left and at its lower level in front of the *thoracic duct*. Furthermore it passes behind the root of the left lung, grooves this lung near its posterior border, and lies behind the pericardium and to the left of the *vena azygos major*. **Aneurism** of this part may *press upon* and obstruct any of the above-mentioned parts, erode the spine and the vertebral ends of the left middle ribs, cause pressure upon and neuralgia of the corresponding left thoracic nerves, and bulge posteriorly to the left of the spine as a pulsating tumor, sometimes of enormous size. It may eventually *burst* on the surface or into the *œsophagus*, left bronchus, pericardium, pleura or posterior mediastinum.

**Variations.**—The arch of the aorta is liable to occasional variations in its position and direction, with or without transposition of the viscera, and to frequent variations in the *number and arrangement of its primary branches*. These variations may decrease the number of primary branches to two or increase them to four, five or six.<sup>1</sup> These anomalies are to be *explained* by abnormalities in the *embryonic development* of these parts from the ventral and dorsal stems and the brachial arches. The only variation of much surgical interest is the

<sup>1</sup> For the above variations see Henle's Anatomy (1868), Vol. III., pp. 203 et seq.; Morris' Anatomy, 2d ed., pp. 471, 472, etc.

origin of the *carotid*, usually the *left*, from the *innominate stem* of the opposite side, in which case it may cross the trachea so as to be in danger of injury in tracheotomy. Not infrequently the *right subclavian* arises from the left end of the arch and passes behind the trachea and oesophagus to reach its normal position.

The *innominate* and *left common carotid*, given off immediately behind the middle of the manubrium, mount thence to the right and left sternoclavicular joints, the former artery dividing opposite the upper border of the right joint. The *innominate artery* ( $1\frac{1}{2}$  to 2 in. long) has the left innominate and right inferior thyroid veins in front; the right innominate vein, pneumogastric nerve, pleura and lung to the right; the trachea behind and to the left, and the left carotid artery to the left. These *relations*, and the occasional origin from it of the *thyroidea ima artery*, are of importance in the *diagnosis of aneurism* of this artery from the pressure symptoms, and in its *ligation* for aneurism of its branches, successful reported cases of which are on the increase. The dangers of the operation itself lie in the important structures in relation with it and in the difficulty of an adequate *exposure*, which may be facilitated by osteoplastic resection of the manubrium (Bardenheuer), or better by a longitudinal median section of the sternum, or its upper half, and the lateral retraction of the divided edges, which exposes the mediastinum and its contents.

The *pulmonary artery*, in its course from the third left to the upper border of the second left chondrosternal junction, projects more or less beyond the left border of the sternum in the second space, where it is exposed to injury. Similarly on the right side the *superior vena cava*, from its origin behind the sternal end of the first costal cartilage to its termination behind that of the third cartilage, lies just to the right of the sternum and ascending aorta, and is exposed to injury in the mesial ends of the first and second spaces. The *left innominate vein* crosses transversely behind the manubrium, just above the aortic arch and just below the episternal notch, and in children and cases of high position of the aortic arch it may project above the bone so as to be exposed to injury in a low tracheotomy or in some thyroidectomies. The *azygos veins* are of practical importance on account of the free *collateral circulation* they afford between the inferior and superior cavæ, in case of obstruction of the former. This is due to their connection with the lumbar, ilio-lumbar, common iliac and renal veins.

The *great, small and least splanchnic nerves*, derived from the fifth to ninth, the tenth to eleventh, and the twelfth thoracic sympathetic ganglia respectively, are connected with the lower thoracic nerves, which supply the abdominal parietes. As they pass to the solar and renal plexuses, which supply the abdominal viscera, they *account for the reflexes* between the abdominal viscera and parietes (see p. 251), and for the pain in some diseases of the liver and stomach, in the region between and over the scapulæ, supplied by the dorsal branches of the thoracic nerves, which are connected with the splanchnics. *Pressure of thoracic tumors or aneurisms upon the sympathetic* may cause

dilatation of the pupil of that side, from irritation of the nerve, or contraction of the pupil, from paralysis of the nerve. As some filaments of the right phrenic nerve pass to the solar plexus and liver, the pain over the tip of the shoulder in liver disease may be explained as a reflex in the acromial filaments from the third, fourth and fifth cervical nerves from which the phrenic is derived.

### The Thoracic Duct.

This is about eighteen inches long from its commencement in the abdomen in the *receptaculum chyli*, opposite the second (or first) lumbar vertebra, to its termination in the neck in the posterior part of the angle of union of the subclavian and internal jugular veins, and is mostly contained within the thorax. Here, after passing through the aortic opening of the diaphragm behind the aorta, it lies between the latter and the vena azygos major in the *posterior mediastinum* up to the level of the fifth thoracic vertebra where it inclines to the left behind the oesophagus, the aortic arch and the left common carotid artery. Thence in the *superior mediastinum* it lies between the oesophagus and the left pleura, behind the left subclavian artery and in front of the vertebral artery. After ascending through the superior thoracic aperture into the *left side of the neck* as high as the seventh cervical vertebra, it arches outward, forward and downward over the apex of the pleura, in front of the subclavian artery, the scalenus anticus muscle and the vertebral vein and behind the left internal jugular vein and the carotid artery, becoming external to the latter. (Fig. 60.)

The highest point of the arch of the thoracic duct normally reaches the level of the transverse process of the sixth cervical vertebra. Although in the thoracic cavity it may be pressed upon by tumors and aneurisms and its rupture is reported by Krabbel in a case of fracture of the ninth thoracic vertebra, followed by a chylous effusion of more than a gallon in the right pleural cavity, it is in the neck that its *surgical interest* lies. Here it has been wounded by stab and bullet wounds and in extensive operations for tumors or tubercular glands of the neck. The near neighborhood of many vital parts would render rapidly fatal most injuries of the duct, unless received during a surgical operation. Under normal anatomical conditions operative injury is very unlikely as the duct does not rise above the level of junction of the two great veins, but it not infrequently rises higher and has been found as high as  $5\frac{1}{2}$  cm. above the sternum (Dietrich). When injured it has been successfully sutured in a few cases and its leakage has been checked by clamps or packing.

Its *obliteration* has occurred without producing any marked symptoms, though experimental ligation in dogs has been followed by rupture of the *receptaculum chyli* or other fatal lesions. A double perfect valve at its entrance into the vein guards against regurgitation of lymph or the entrance of blood. It may enter the veins as a delta. It receives the lymph and chyle from all parts of the body except the right upper extremity, the right side of the chest, head and neck and

## PLATE XXVII.

FIG. 60.

Topography of the thoracic duct in the neck.

(Zuckerkandl.)

the convex surface of the liver, which is returned by the right lymphatic duct to a corresponding point of the veins on the right side. Its injury is of less moment.

### The Oesophagus.

Like the thoracic duct the oesophagus is contained partly in the neck and abdomen but mostly in the thoracic cavity, in the superior and posterior mediastina. The *level of the commencement* of the oesophagus, as the continuation of the pharynx, depends, like that of the trachea, on the position of the head and neck and varies from the fifth to the sixth or seventh cervical vertebrae. In a position midway between flexion and extension of the neck its upper end, behind the lower border of the cricoid cartilage, is *opposite the sixth cervical vertebra*. Its *lower end* passes through the diaphragm, opposite the tenth thoracic vertebra, to end in the stomach, opposite the eleventh vertebra. Its *length* (23 to 26 cm.) averages  $9\frac{1}{2}$  to 10 inches, which with the distance of its upper end from the upper incisor teeth, 6 in., makes the average distance from the latter to the stomach  $15\frac{1}{2}$  to 16 in. (17 cm. in the new-born (Mouton). The length of the cervical portion, *i. e.*, above the episternal notch or the second thoracic intervertebral disc, averages 5 to 7 cm. and ranges between  $4\frac{1}{2}$  and  $8\frac{1}{2}$  cm. (Tillaux), varying with the length and position of the neck.

Its *direction* (Fig. 58) is not straight. It *inclines to the left* in the neck but is pressed back to the median line by the left end of the aortic arch, opposite the fourth thoracic vertebra. Below this it again curves slightly to the left, so that its diaphragmatic orifice is normally somewhat to the left of the median line and to the left and in front of the aorta. In the sagittal plane it follows the curved line of the vertebrae to the fourth thoracic vertebra, below which it gradually leaves the vertebrae and passes more vertically to its diaphragmatic orifice. None of its curves are of sufficient extent or degree to interfere with the passage of bougies or instruments.

**The lumen** of the oesophagus, except during the act of swallowing or vomiting, is always closed in the cervical portion, sometimes closed and sometimes open in the thoracic portion, according as the stomach is full or empty of gas or fluid. The *caliber* of the oesophagus, which is the narrowest section of the alimentary canal, varies and presents **three constricted parts**, one at its commencement, another 7 cm. below, and the third at its passage through the diaphragm, 22 cm. below. The latter is not a narrowing of the tube itself but is due to the fibers of the diaphragm which surround it and form a kind of canal for it. The *lowest constriction* is the *narrowest*, measuring 12 mm. in diameter as compared to 14 mm. for the upper two, but it is *more distensible*, allowing of rapid dilatation to 22 mm., the other two to 18 or 19 mm.

It follows that in a normal oesophagus a **bougie** 14 mm. in diameter should pass easily, otherwise there is a stenosis, and that in *dilating* the oesophagus an instrument of 18 mm. diameter should be the limit. In the new-born the *caliber* of the oesophagus is 4 mm. On account of a *spasmodic muscular contraction* the introduction of a bougie may be

hindered at the upper end of the oesophagus and lower down it may be suddenly held in the same way. During the muscular spasm the sound should be left at rest, as the attempt to force it increases the spasm. Owing to the firm relations in front of and behind the oesophagus, *i. e.*, trachea and vertebrae, it is less distensible in these directions than laterally, as seen in sword swallowing. Accordingly some olive-tipped bougies are made flattened.

Any **foreign body** which will pass the upper two narrow points will probably pass the lower one. Foreign bodies are therefore most likely to be *arrested* at the upper end of the oesophagus, or the lower end of the pharynx, where the predominance of striped muscle tissue in the walls often allows of their being returned to the mouth by a spasmodic muscular action. If this fails they may be removed by some form of oesophagus forceps, as may also those bodies arrested at the *second narrow point*, which begins  $3\frac{1}{2}$  cm. and is narrowest 7 cm. below. If the forceps fails to remove a body arrested at the second constriction the alternatives present of pushing it down to the stomach or removing it by an external oesophagotomy.

**Strictures** of the oesophagus, both malignant and cicatricial, are most likely to be found at one of the constricted points. The *cicatricial variety* occurs most frequently at the narrow points because the corrosive fluid swallowed takes slightly longer in passing these points and hence acts more intensively on the oesophageal wall, causing deeper ulceration and greater subsequent contraction. **Cancerous stricture** is most common at the upper or lower ends, and in the latter case the symptoms are not infrequently referred to the upper end.

The **lymphatics** enter the mediastinal and cervical lymphatic nodes so that if cancer of the oesophagus is suspected we should examine the nodes at the root of the neck.

The **relations** of the oesophagus are especially important at the *narrow points* where lesions are likely to occur and in the neck where oesophagotomy is done and where other operations and injuries may concern it. The **second constriction** is about behind the aortic arch and *foreign bodies* arrested here have *ulcerated* through into the aorta, causing immediate and fatal hemorrhage. Thus a five-franc coin (Musée Dupuytren), a fish bone (Lancet, 1871), etc., have been reported ulcerating into the aorta, and a piece of bone impacted in the oesophagus has been reported (Ogle, in Path. Soc. Trans., Vol. IV.) ulcerating into an intervertebral disc and setting up a fatal disease of the cord. **Aneurism** of the aortic arch or descending aorta may press upon the oesophagus and *simulate stricture* of its lumen. A bougie passed under such conditions may penetrate the sac and bring on a sudden fatal bleeding. Similarly an impacted body or an epithelioma has ulcerated into the lower end of the trachea, the left bronchus or the right pulmonary artery, which also lies in front of the oesophagus. An instrument passed in case of a carcinomatous stricture of the oesophagus may readily pierce the softened wall of the tube and penetrate the trachea or left bronchus, setting up a septic pneu-

PLATE XXVIII.

FIG. 61.

Transverse horizontal section of the body at the level  
of the 8th thoracic vertebra. (Joessel.)

monia, or it may wound the aorta, pericardium, pleura, etc., with a fatal result. The contiguity of the oesophagus with the membranous wall of the trachea and with the left bronchus explains the effect of foreign bodies in the one producing symptoms of obstruction referable to the other, so that tracheotomy has been done for a foreign body in the oesophagus. Of course foreign bodies, especially sharp or irregular ones, may become arrested elsewhere than at the narrowest points.

The *aorta* winds spirally around the oesophagus, being in front above, then to the left, then behind and finally behind and to the right. *Below the aortic arch* the oesophagus is just behind the bronchial glands and the pericardium and corresponds to the left auricle, so that in enlargement of the heart or distension of the pericardium with fluid the patient may be unable to swallow with comfort in the supine position. The oesophagus lies between the two *pleural sacs* but in more direct contact with the left above and the right below. Hence carcinoma of the oesophagus is said to extend to the right lung and pleura more often than to the left, though I have observed it on the left side. The *thoracic duct* is to the right below, to the left above and crosses behind it about the fourth or fifth thoracic vertebra. Loose cellular tissue, continuous with that behind the pharynx, connects the oesophagus with the vertebrae and along this a retropharyngeal abscess or a deep abscess of the neck may descend into the mediastinum and press upon the oesophagus.

In the neck its relations are of importance especially *on the left side*, on which *external oesophagotomy* is performed as the oesophagus inclines to the left. In this operation the left recurrent laryngeal nerve, the inferior thyroid artery and the left lobe of the thyroid gland, which lie in front of the left side of the oesophagus, must be carefully avoided. After *incising* along the anterior border of the sternomastoid, from the thyroid cartilage downward, this muscle and the carotid sheath are retracted outward, the other structures inward. On the *right side* the carotid sheath is further removed from the oesophagus and the recurrent laryngeal nerve runs more along its lateral border. The modern operation of gastrostomy gives good results and is far preferable to oesophagostomy. In cicatricial strictures there is a pouch-like dilatation of the oesophagus above the stricture, the opening of which is usually eccentric so as to prevent the passage of bougies. Hence the retrograde dilatation through an opening in the stomach is the best method.<sup>1</sup> Foreign bodies impacted at the lower end may be removed by gastrotomy (Richardson).

*Congenitally* the oesophagus may be deficient in part and open into the trachea below or, more rarely, above. There may also be a tracheo-oesophageal fistula, an annular stricture, a dilatation or a doubling or division of the tube. True *diverticula*, both pulsion and traction diverticula, are acquired, the former due to a hernia of the mucosa through the inferior constrictor of the pharynx at the upper end of the oesophagus or the lower end of the pharynx, the latter due to the contraction of scar tissue connecting the oesophagus with surrounding parts (*i. e.*, bronchial glands, etc.).

<sup>1</sup>See article by the writer in Annals of Surgery, March, 1895.

## CHAPTER IV.

### THE ABDOMEN.

**Shape.**—In general the abdomen is barrel-shaped, flattened from before backwards, and wider below than above. In the adult *female* the larger circumference below than above is due to the size of the pelvis and is still more marked when the upper part has been compressed by corsets. In *childhood*, owing to the incomplete development of the pelvis, the abdomen is larger above than below, especially in its transverse diameter. The **height** of the abdomen in the female is greater than in the male owing to the greater size of the lumbar vertebrae. The **long axis** of the abdominal cavity is not vertical but oblique from above downwards and to the right, owing to the greater height of the diaphragm on the right side. The *intraabdominal pressure* acting most strongly in this line is said to account for the greater frequency of hernia on the right than on the left side.

*In fat subjects* the abdomen protrudes to a varying degree in front, owing to the deposit of fat among the abdominal viscera and the peritoneal folds and to the large amount of subcutaneous adipose tissue.

*In infants* the abdomen protrudes in front, owing to the relatively large size of the liver and the small size of the pelvis, which crowds the pelvic viscera (bladder, rectum, etc.), partly up into the abdomen. The latter condition, apart from the amount of fat, accounts for the protrusion of the abdomen in children until the pelvis enlarges at the approach of puberty.

Certain physiological and pathological conditions cause a general or local protrusion of the abdomen, such as pregnancy, ascites, and tumors of the abdominal contents or walls. After such long-continued distension, an undue amount of prominence or pendulousness often remains.

In cases of great *emaciation* from starvation or wasting disease, the contour of the abdomen is much depressed in front and especially just beneath the costal margin where the slight normal median depression, known as the "*pit of the stomach*" (or *scrofula cordis*) may become so marked that, in the recumbent position, the wall sinks away almost vertically from the costal margin and the prominence of the vertebrae is noticeable. In tubercular meningitis the abdomen shows a "boat-shaped" depression in front, owing to the contraction of the empty bowels.

**Boundaries.**—The abdomen, including the pelvis, is bounded *above* by the diaphragm, which separates it from the thorax, *below* by the pelvic floor. A *plane* drawn through the base of the ensiform carti-

lage in front and the tenth thoracic spine behind suggests the upper limit of the cavity, which, however, ascends even higher than this into the vault of the diaphragm.

The actual upper limit of the abdomen, extending up as it does under cover of the lower ribs and costal cartilages, is higher than the apparent limit, *i. e.*, the costal margin.

It is *bounded behind* by the lumbar vertebræ, sacrum, lower two or three ribs, diaphragm, lumbar muscles and the posterior portions of the ilia; *in front*, by the free ends of the false ribs and costal cartilages, the symphysis, the body and rami of the pubis, and the ventral abdominal muscles; *laterally*, by the lower ribs and diaphragm, the ilia and ischia, and the fleshy portions of the flat abdominal muscles.

Except for operations on subdiaphragmatic and liver abscesses, after suture of the diaphragm to the opening in the costal pleura, no operations are done through the upper boundary or diaphragm. Many operations are performed through the perineum and the pelvic floor on the rectum, female pelvic organs, and male genito-urinary organs. Hahn's operation for gastrostomy is done through the eighth intercostal space, and occasionally the iliac fossa has been perforated for drainage of an abscess. Otherwise abdominal operations are performed through the soft parts which indicate the apparent limit of the abdomen and form an hexagonal area bounded by the costal cartilages of the six lower ribs and by the twelfth ribs above, the transverse processes of the lumbar vertebræ behind, and by the iliac and pubic crests and Poupart's ligament below.

### Superficial Markings and Landmarks.

**Bony Points.**—Superiorly the *ensiform cartilage* and the diverging margins of the *costal cartilages* are often visible and always palpable. The tip of the ensiform cartilage is about on a line with the lower part of the tenth thoracic vertebra. There is a palpable *notch on the costal margin* between the tip of the tenth and the border of the ninth costal cartilage, which is a useful landmark.

The tips of the *eleventh and twelfth costal cartilages* lie free between the abdominal muscles. They can be readily felt except in fat subjects, but it is never safe to rely upon palpation alone in determining the twelfth rib (see p. 282) and the ribs should always be counted from above to locate the twelfth rib in lumbar operations.

As the *spines* of the *lumbar vertebræ* closely correspond with the level of their bodies, some of the relations of the latter may here be given, according to Holden and Windle:

First lumbar vertebra and spine: pancreas, pelvis of kidney with endings of renal arteries. Junction of first and second: end of spinal cord. Third: lower border of kidney. Junction of third and fourth: umbilicus. Fourth: highest part of iliac crest, bifurcation of aorta. Third sacral vertebra: limit of spinal membranes.

The anterior superior iliac spine is an important landmark in determining the length of the lower extremities in fractures of the

femur and in injuries and diseases about the hip joint. On a line between it and the umbilicus, at the outer border of the rectus is "*McBurney's point*," commonly the point of greatest tenderness in appendicitis. This spine is at the outer extremity of the *inguinal fold* (due to Poupart's ligament) where in thin subjects it is visible as a prominence, in fat subjects as a depression, and in all subjects it is palpable. It lies in a plane about on a level with the top of the promontory of the sacrum, in the erect position.

Extending outward and upward from this spine the sinuous *iliac crest* may be felt throughout, except dorsally in very fat subjects. In muscular subjects it lies in a groove (*iliac furrow*) below the fleshy fibers of the external oblique muscle. It ends dorsally in the *posterior superior iliac spine*, often difficult to feel, but indicated by a slight depression on a level with the spinous process of the second sacral vertebra.

The pubic spine is another bony landmark of special importance in the anatomy of hernia, lying external to the neck of an inguinal hernia, internal to that of a femoral. It lies at the inner end of the inguinal furrow and Poupart's ligament. It is readily palpable except in fat subjects in whom it may be found by following up the adductor longus tendon, and in the male, by invaginating the serotum and thus getting beneath the subcutaneous fat. It lies in the same horizontal plane with the upper border of the great trochanter. Between it and the symphysis pubis the *pubic crest* may be felt, except in the obese.

**Lines, Muscles, etc.**—The *linea alba* (see also p. 245) corresponding to the fibrous interval between the two recti muscles, is marked by a slight median groove (*the abdominal furrow*) from the *infrasternal depression* (pit of the stomach), below the ensiform cartilage, to just below the umbilicus. Below this it is not visible owing to the close approximation of the recti muscles, the lower ends of which are concealed by a small amount of fat.

The *umbilicus* (see also p. 257) lies three fourths to one inch above the bifurcation of the aorta, on a line connecting the highest points of the iliac crests and on a level with the disc between the third and fourth lumbar vertebrae, and the lower end of the third lumbar spine. Whereas at birth it lies below the center of the body, in the adult it is above this point, which lies nearer the symphysis pubis. It always lies below the center of the linea alba, about the junction of its upper three fifths with the lower two fifths, though it varies in position with the obesity of the subject.

The *linea semilunaris* (see also p. 244) corresponds to the outer border of each rectus muscle and may be well seen, when that muscle is in action, as a slightly curved line convex laterally, from the tip of the ninth costal cartilage to the pubic spine. It lies, on the average, about three inches laterally from the umbilicus, and above that level it is indicated by a shallow depression which ends above at the margin of the thorax in a somewhat triangular *infracostal fossa*.

When in action the rectus presents three slight transverse grooves extending between the linea alba and semilunaris and representing the linea transversæ (see also p. 242). One is about the tip of the ensiform cartilage, a second midway between this and the navel, the third, less marked, at the navel and occasionally a fourth below the navel, in the outer half of the muscle.

The inguinal furrow corresponds to Poupart's ligament, and is an important landmark in the surgical anatomy of hernia.

Lateral to the linea semilunaris the upper part of the fleshy portion of the *external oblique* is seen interdigitating with the serratus magnus in a zigzag line directed obliquely downward and backward. Its prominence above the iliac crest forms the iliac furrow which lies over the iliac crest.

The superficial epigastric vein (see also p. 249) is often visible through the skin, especially if enlarged, when it may be seen to communicate with another vein (thoracico-epigastric) which joins the axillary vein, as well as with the superior epigastric vein of the internal mammary.

### THE ANTERIOR ABDOMINAL WALL.

The lateral limits may be taken to be the lateral border of the external oblique muscle, which alone of the flat abdominal muscles has a free lateral margin between the thorax and the iliac crest. The soft parts may be studied by layers and then certain important areas considered separately.

The skin is thin and loosely attached to the tissues beneath, except around the umbilicus and, to a less extent, in the median line. In the male the skin, especially above the pubis and near the median line, is often beset with hairs. The numerous hair follicles may make it difficult to make the skin reasonably aseptic. The cleavage lines of the skin are in general parallel with the course of the lower intercostal and the upper lumbar nerves. When the skin has been greatly stretched from abdominal distension, scar-like silvery streaks (*striæ gravidarum*) appear, especially in the lower part where the distension is usually greatest. They are due to atrophy of the skin from stretching, but are not evidence of pregnancy, for they may follow any great distension.

The superficial fascia, unlike the subcutaneous tissue in most regions, consists of two layers which are most distinct in the lower half of the abdomen. Between the two layers at the groin are the superficial blood vessels and the oblique set of the superficial inguinal lymph nodes. Both layers are continued on to the external genitals and the perineum.

The superficial layer of the superficial fascia contains the *subcutaneous fat*, the deposit of which is greatest toward the middle and lower part, reaching its maximum in the female over and about the pubis, as the *mons veneris*. The fatty deposit may reach such a thickness (six inches has been found) as to make examination of the abdominal wall or contents impossible, and even to contraindicate operation.

The thicker the layer, the longer the incision required. The fat of the abdominal wall acts as a non-conductor to prevent changes of temperature affecting the viscera and thus serves as a "cholera band." The comparative thickness of the belly wall in different subjects depends upon the amount of this fat rather than upon the thickness of the muscles.

This layer is continuous with the superficial fascia on all sides. *In thin subjects* the fat may be so small in amount that not only are the muscles and superficial markings very clearly seen, but intestinal peristalsis may be felt or observed and visceral tumors may be readily outlined through the thin wall. *In very fat subjects*, two *deep folds*, involving the skin and this layer, run transversely across the abdomen, one at the umbilicus concealing it, and the other just above the pubis. Where the latter crosses the median line the trocar should be introduced in tapping the bladder. These folds are due to a slight absorption of fat, due to the pressure of the folding of the skin in bending forward.

**The deep layer** of the superficial fascia consists of a firm membrane containing elastic fibers. It is firmly *attached* to the deeper parts in the median line down to the symphysis and to the fascia lata just below Poupart's ligament and along the iliac crest. Between the symphysis and the pubic spines it is not attached to the underlying parts but, uniting with the superficial layer which here has lost its fat, it passes down to become continuous with the dartos of the scrotum and penis. Many interesting clinical facts depend upon this arrangement. Subcutaneous emphysema due to injuries of the chest, lipomata, blood or pus beneath this layer are arrested at the median line, the inguinal fold and the iliac crest and are prevented from reaching the thigh or the buttock by reason of its firm attachment to deeper parts. They may however pass down into the scrotum between the symphysis and the pubic spines. If the same conditions occur superficial to this layer, they may readily extend in all directions.

Tillaux describes a lipoma beneath the deep layer in the inguinal region, which was thought to be an inguinal hernia, but was shown not to be by reason of the emptiness of the inguinal canal.

In like manner extravasated urine, pus or blood in the scrotum may ascend on to the abdomen, between the pubic spines and the symphysis, but cannot cross the median line or descend onto the thighs without first perforating this layer. Between the two layers lie the superficial vessels, hence we may remember in making incisions that the fatty layer is free from large blood vessels.

Of little surgical importance, as far as the abdomen is concerned, is a *thin cellular fascia* covering the external oblique muscle. In the inguinal region this seems to be continuous with the *intercolumnar fibers* and the fascia which, binding them together, is continued down into the scrotum as the *external spermatic fascia*, one of the coverings of the cord or of an inguinal hernia.

**The muscular layers** present vertically directed fibers mesially, in the rectus and pyramidalis muscles, and obliquely directed fibers

PLATE XXIX.

FIG. 62.

Muscles, vessels and nerves of the anterior  
abdominal wall. (Joessel.)

laterally, in the external and internal oblique and transversalis muscles. The strength of the abdominal walls depends chiefly upon the muscles. It should be remembered, however, that these muscles are much *thinner*, in most cases, than one would be led to suppose from their description in text-books.

The flat *fleshy bellies* of the *oblique muscles* are found largely at the sides, where they fill in the interval between the vertical muscles at the back and in front, except for a narrow strip along the outer border of the rectus where their aponeuroses form the fibrous semilunar line, and a small *semilunar area* beneath the conjoined tendon.

The *fleshy portion* of the *external oblique* terminates in a right angle, readily seen in muscular subjects some distance from the border of the rectus. It lies above a horizontal line drawn from a point on the iliac crest one to two inches behind the anterior superior iliac spine, and external to a vertical line from the lowest point of the ninth rib. It also lies somewhat above a line connecting the anterior superior iliac spine with the umbilicus; hence only the upper part of the usual oblique incisions in this region involves the fleshy fibers of this muscle. It is the only one of the three flat muscles in question which has a *free posterior border*, between its attachment to the last rib and the middle of the iliac crest, the other two muscles being connected posteriorly with the lumbar fascia. This free lateral border may be overlapped throughout by the latissimus dorsi, or a triangular interval of varying size may be left between these two muscles and above the iliac crest, the *triangle of Petit*, whose floor is formed by the internal oblique. This is a point of least resistance where abscesses may point or a rare form of hernia may occur (*lumbar hernia*).

The *direction* of the muscular and aponeurotic fibers of the *external oblique* is approximately at right angles to the line connecting the anterior superior iliac spine and the umbilicus.

The *fleshy portion* of the *internal oblique* extends beyond that of the *external* both mesially and laterally, and especially below and mesially. The *lower fibers*, blended with those of the *transversalis* and directed downward and inward, arch over the inguinal canal to be inserted into the inner inch of the iliopectineal line as the *conjoined tendon*. This covers an area in the inguinal region otherwise wanting in muscular tissue, but leaves a narrow uncovered space between its lower curved margin and the inner half of Poupart's ligament (see *Inguinal Region*, pp. 260). The fleshy fibers of the *internal oblique* are *directed* in a fan-shaped manner but, except those forming the *conjoined tendon*, the general direction is upward and inward, crossing those of the *external oblique* nearly at a right angle, like bars of lattice work. They do not reach above a horizontal line drawn below the tip of the last rib, nor in front of a line drawn upward and a little outward from the center of Poupart's ligament, except for the *conjoined tendon*.

The *fleshy fibers* of the *transversalis*, *directed* for the most part transversely, present mesially a concave margin, approaching nearer the

middle line above and below. The *upper fibers* pass beneath the rectus and therefore underlie the semilunar line in the upper part, the *lower fibers* take part in forming the *conjoined tendon* but arch high above the inguinal canal and give no covering to the cord or a hernia, as does the internal oblique by means of the cremasteric fascia.

These three flat abdominal muscles are *separated* from one another by a certain amount of loose connective tissue, which favors the spread of inflammation from a wound or of a *mural abscess* from spinal caries, etc. Such abscesses will be limited by the semilunar line mesially, the erector spinal laterally, Poupart's ligament below, and the bony thorax above, and usually work down to the iliac crest, the inguinal fold, or along the inguinal canal into the scrotum or labia.

Between the internal oblique and transversalis muscles run the main trunks of the lower *thoracic* and the upper *lumbar nerves* that supply the muscles and skin of the abdomen.

The different direction and the *crossing of the fibers* of the oblique and transversalis muscles has the following *practical results*: (1) It strengthens the abdominal wall and greatly reduces the possibility of a hernia between the separated fibers of the muscles. (2) It permits contraction of the abdominal wall in every direction and thus, (3) increases the amount of abdominal pressure for the expulsion of urine, faeces, and the fetus. (4) It produces greater approximation in the movements of the movable bony boundaries of the abdomen. (5) It affords a landmark or an index as to the depth of an incision in operations.

Before studying the aponeuroses, or tendons, of the above muscles it is convenient to consider the vertical muscles, the rectus and pyriformis.

**The two recti** run vertically the entire length of the abdominal parieties on either side of the median line. They are much narrower below than above, and in the upper two thirds are said to be about as broad as the hand, at the heads of the metacarpal bones. The longitudinal fibers are *interrupted* by the *fibrous intersections* at the *lineæ transversæ*, so that they do not run the entire length of the muscle. The *lineæ transversæ* represent the septa which divide the muscles of the abdomen at intervals in the lower vertebrates and the abdominal ribs of the crocodile. The latter analogy is indicated by the relation of some of the lower thoracic nerves to the intersections, similar to that of these nerves to the ribs. The intersections serve the important function of holding together the fibers of the muscle and preventing the formation of ventral hernia in cases of great abdominal distension from pregnancy, etc., but they do not offer serious resistance to the longitudinal separation of the fibers in a vertical incision through the rectus. They prevent the extensive retraction after division of the muscle which would result if the fibers were uninterrupted. Resembling as they do transverse scars they indicate that transverse incisions of this muscle, if healed by a proper cicatrix, only increase the number of such transverse intersections which nature provides to strengthen the muscle and therefore can do no harm. These fibrous intersections are *adherent* to

the front but not to the back of the sheath of the rectus; hence *suppuration* in the rectus may be *limited* to the interval between two transverse intersections, or below the lower one, though it may extend along the entire dorsal surface where they are not connected with the sheath.

By means of this connection of the intersections with the sheath, the action of the rectus may affect the latter and the aponeuroses of which it is formed, thus diffusing its action. They allow part of the muscle to act at a time, as, for example, the lower part in micturition.

Similarly the rectus may be the seat of a form of **phantom tumor** in hysterical subjects, due to a contraction of a part of the muscle, usually to a segment between two intersections. The irregular contraction of other abdominal muscles may also cause a phantom tumor. When associated with distension of the bowels from flatus or faeces and with abdominal or pelvic symptoms such tumors may mislead. The relaxation of the contraction from an anaesthetic, or otherwise, causes the tumor to disappear. They are said to be more common in the left rectus. The position of the intersections has already been given. (See page 239.)

The fibers of the rectus are rarely *torn* by muscular violence and in opisthotonus.

*Below the umbilicus* the two *recti* are so *close* together that it is scarcely possible to make a median incision without exposing the mesial fibers of one or both.

The **pyramidalis muscles** lie beneath the sheath of the recti, in front of the latter muscles and separated from them by a layer of fibrous tissue. They are inserted into the linea alba one third to one half the distance between the symphysis and the umbilicus and, when large, may entirely cover the median line, so that division of their fleshy fibers cannot be avoided in a median incision. They may be absent or unusually small on one or both sides.

The **anterior aponeuroses of the oblique and transversalis muscles** extend from the mesial borders of the fleshy portion of these muscles to the median line, where they unite with those of the opposite side to form the *linea alba*. Thus the transversalis muscles of the two sides may be considered a double-bellied muscle with an intervening tendon, and the same may be said of the external oblique on one side with the internal oblique of the opposite side, for their fibers run in a similar direction. The aponeurosis of the external oblique is widest below, that of the internal oblique above, and that of the transversalis in the middle.

The **inguinal or Poupart's ligament** is formed of the thickened lower fibers of the aponeurosis of the external oblique which extend from the anterior superior iliac spine to the pubic spine.

Beneath it the ilio-psoas muscle, the femoral vessels, the anterior crural, the external cutaneous, and the crural branch of the genito-crural nerves, together with the lymphatics pass from the pelvis into the thigh. It is somewhat *infolded* on itself so as to form a kind of gutter, the concavity of which is directed upward and inward and the dorsal

margin of which is loosely connected with the transversalis fascia and, in the outer part, with the iliac fascia also. (Fig. 63.)

*Inferiorly* it is firmly connected with the fascia lata of the thigh which, in the extended position of the hip, pulls it downward so as to make it *convex downward*. Hence in **palpation of the abdomen**, as well as in the reduction of hernia, the thighs are flexed on the pelvis which relaxes the traction of the fascia lata on Poupart's ligament. This relaxes the abdominal walls by relaxing the aponeurosis of the external oblique and the transversalis fascia, as well as the internal oblique and transversalis muscles which arise from the outer half of Poupart's ligament. In addition, the stomach, bowels and bladder should be empty to facilitate palpation.

Poupart's ligament corresponds to the *inguinal fold*, and is an important *landmark* in the surgical anatomy of hernia, as well as in the operations performed in the iliac region of the abdominal parietes. Some of its fibers pass nearly directly backward to be attached to the inner inch or so of the ilio-pubic line. These form *Gimbernat's ligament* whose free, concave, external margin is at the inner border of the crural canal (see p. 271). The latter ligament forms part of the septum between the pelvis and the thigh. Upon the concave upper surface of Poupart's ligament lie the structures which pass out at the external abdominal ring.

Internal to the pubic spine the fibers of the external oblique aponeurosis are attached to the crest of the pubes. But some of its fibers, known as the **triangular ligament or fascia**, decussating with fibers of the aponeurosis of the opposite side, cross the median line, pass behind and strengthen the opposite external abdominal ring and are attached to the pubic crest and the ilio-pectineal line of that side, in connection with Gimbernat's ligament.

The tendinous fibers of insertion of the conjoined tendon are inserted into the ilio-pectineal line behind Gimbernat's and the triangular ligaments. This tendon lies behind the external abdominal ring, strengthening an otherwise weak spot.

**The semilunar line** (see also p. 238) indicates the line along which the abdominal aponeuroses divide to form the sheath of the rectus. Along this line, lying between the rectus and the fleshy portion of the lateral muscles, the abdominal wall is composed only of the fibrous tissue of the abdominal aponeuroses, except above where fleshy fibers of the transversalis pass behind it. It is *devoid of large vessels*, except low down where the deep epigastric vessels cross it, hence it is sometimes chosen for incision or paracentesis.

It is concave mesially corresponding to the outer border of the rectus. The upper end of the line is at or slightly internal to the point where the gall-bladder comes in contact with the abdominal wall. Above a level  $1\frac{1}{2}$  inches below the umbilicus, the semilunar lines nearly correspond to vertical lines erected from the middle of Poupart's ligament. "*McBurney's Point*" is on the semilunar line where it is crossed by the line connecting the anterior superior iliac spine with

# PLATE XXX.

FIG. 64.

Diagrammatic transverse section of anterior abdominal wall. Upper figure above, lower figure below the semi-lunar fold of Douglas. (Joessel.)

the umbilicus. This point corresponds about to the base of the appendix.

The sheath of the rectus (Fig. 64) is formed by the aponeuroses of the three lateral muscles. That of the internal oblique splits along the semilunar line to pass partly in front and partly behind the muscle. This arrangement holds in the upper three fourths of the muscle, but in the lower fourth, a little above midway between the umbilicus and the symphysis, all three aponeuroses pass in front. The lower limit of the dorsal part of the sheath formed by the aponeuroses is concave downward, and known as the **semilunar fold of Douglas**. Below this a delicate fascia is described as passing down behind the rectus to the bladder (*fascia Retzi*), in addition to the *transversalis fascia* which is here firm and thickened and takes the place of the dorsal layer of the sheath.

At the fold of Douglas the *deep epigastric vessels* pass within the rectus sheath in their upward course. The *lateral extremities* of the folds of Douglas descend as thickened bands or pillars, the inner pillar to the symphysis, the outer, or ligament of Hesselbach (Braune), splits to enclose the internal abdominal ring, being attached internally to the horizontal ramus of the pubis (and to the pectineal fascia), and externally to the iliac fascia (over the psoas) and to the transversalis muscle where it arises from Poupart's ligament.

The aponeurotic layers which form the ventral and dorsal layers of the sheaths of the recti uniting along the median borders of the muscles to complete the sheaths join one another to form a *median fibrous raphé*, the **linea alba** (see also p. 238). From the ensiform cartilage to, and a little below the umbilicus it is wide, apparent and easily found, measuring about  $\frac{1}{4}$  inch in width below the ensiform cartilage and  $\frac{2}{3}$  inch near the umbilicus. Below the umbilicus it rapidly narrows, and thence down to the symphysis it is merely the narrow fibrous interval between the sheaths of the two recti where their sheaths coalesce. This fibrous interval may be difficult to find, and in fact it may be said that there is practically no linea alba below the umbilicus, and that it is rarely possible to incise here without exposing the margins of one or both recti muscles, so that the knife need only follow the median line and disregard the linea alba. Just above the symphysis the linea alba expands into a narrow triangular band, the *adminiculum*, only visible on the dorsal surface of the abdominal wall. The interval between the two muscles is slightly more marked just above the symphysis in front also, so that it has been suggested to incise from below upwards in this part of the linea alba, for the reason that it may be more easily found.

In pregnancy or in abdominal distension from other causes the linea alba becomes much wider, owing to the separation of the recti, reaching  $3\frac{3}{5}$  inches at the umbilicus and  $1\frac{1}{5}$  inches at the narrowest part (Cruveillier). I have also observed a congenital separation of the recti with a corresponding widening of the linea alba and a slight umbilical hernia in an otherwise healthy child. The fingers could

readily be thrust between the recti, below the umbilicus. A similar condition may exist in "pot-bellied," rickety children. In such cases a ventral hernia may occasionally occur between the two recti muscles. Ventral hernia of the linea alba is usually due to the enlargement of small openings which exist normally, some of them for the passage of small nerves and vessels. Such a hernia should not be confounded with small lipomata which may grow from the subperitoneal tissue through these openings.

The fibrous tissue composing the linea alba is thin and compact, and cannot be separated into layers corresponding to the three aponeuroses which unite from either side to form it. As there are no vessels of any size in the linea alba it is often selected for incision or paracentesis.

*Contraction of the muscles* of the abdominal wall make the latter as hard as a board. In this condition they *protect the viscera* within from sudden movement or pressure in acute peritonitis, or from a blow. If a *blow* is expected the instinctively contracted and rigid abdominal muscles protect the viscera from injury like a firm but elastic rubber plate, though they themselves may be bruised or even torn. On the contrary an unexpected blow upon a flaccid abdomen may seriously wound a viscus without visibly affecting the belly wall, the latter escaping injury by being very freely movable over the viscera. It is impossible to tell the severity of the blow or the seriousness of the injury from outward inspection. In such cases a thick padding of fat in the belly wall or omentum helps to protect the viscera from injury.

On account of the *tonic contraction* of the abdominal muscles a positive pressure (*intra-abdominal pressure*) normally exists in the abdomen, and this pressure is increased by the descent of the diaphragm in inspiration. For this reason the abdominal viscera readily protrude through a penetrating wound of the belly wall. Diminution of this pressure and weakness of the muscles which cause it is an important element in constipation, difficult labor, pelvic displacements in women, etc.

**The transversalis fascia**, not to be confounded with the transversalis aponeurosis, lines the deep surface of the transversalis muscles and their anterior aponeuroses, and is *continuous with* the fascia lining the other parts of the abdominal walls.

It is very thin *above* the umbilical level, where it passes up to become continuous with a delicate fascia on the under surface of the diaphragm and *laterally* it is continuous with the anterior layer of the lumbar fascia. *Below the umbilicus* it becomes thicker and firmer as we trace it downward, and here it is important in strengthening the abdominal wall where the tendency to hernia is greatest. This is especially so mesially, where it supplies the place of the posterior sheath of the rectus below the semilunar fold of Douglas, and laterally between the inner half of Poupart's ligament and the conjoined tendon, where it is very strong and strengthens an otherwise weak spot.

It is *attached to* the inner lip of the iliac crest and to the outer half

of Poupart's ligament, blending with the iliac fascia. Beneath the inner half of Poupart's ligament, to which it is but loosely attached, it is thickened by transverse fibers to form the *deep femoral arch*, and is continued down into the thigh to form the front of the *femoral sheath*. More internally it is attached to the iliopectineal line, behind the conjoined tendon, and to the crest of the pubes, where it is continuous with the pelvic fascia.

In the male, a pouch of this fascia shaped like a funnel, hence called the *infundibuliform fascia*, descends in foetal life with the peritoneal processus vaginalis along the inguinal canal into the scrotum, forming one of the coverings of the spermatic cord and the testis. After the descent of the testis this pouch contracts, so that it closely surrounds the cord in its passage through the inguinal canal, leaving a slight depression with a crescentic mesial border at the internal ring, where the fascia is called infundibuliform. As the transversalis fascia lines the antero-lateral abdominal walls, no hernia can occur here without receiving a covering from it.

In *incisions* this fascia may possibly be mistaken for the peritoneum, and the subperitoneal fat beneath it for the underlying omentum.

This fascia will *direct* the course of *an abscess*, etc., lying superficial to it. Such an abscess would be disposed to spread downward where it would be checked by and point above the attachment of the fascia to the iliac crest and the outer half of Poupart's ligament, or more internally it might run along the inguinal canal into the scrotum.

**The subperitoneal connective tissue** is a delicate layer of loose connective tissue containing a varying amount of *fat*, which separates the parietal peritoneum from the fascia lining the abdominal walls.

Along the linea alba and at the umbilicus it binds the transversalis fascia and peritoneum closely together. Elsewhere it is more loose and abundant, and *its looseness* favors the spread of abscess, etc., on the one hand, and on the other hand allows the peritoneum to be stripped up from the fascia in extraperitoneal operations on the iliac vessels, ureter, etc.

Owing to the ease with which this tissue allows the peritoneum to be stripped up care is required to avoid this in abdominal incisions and especially in operations for ovarian cysts, where the peritoneum may be mistaken for the cyst wall and extensively detached. In abdominal incisions it is often best to fasten the peritoneum to the overlying layers by a suture or two, so that the manipulations through the wound will not strip it up. The presence of this tissue, especially when thick or containing *fat*, is useful as a *landmark* in abdominal incisions to indicate that the peritoneum has been reached. It should be borne in mind that, in some cases and localities, the amount of fat may be considerable so as not to mistake it for the omentum, as sometimes happens. The amount of fat is greatest in the inguinal, iliac, and lumbar regions, in the latter furnishing the perinephritic fat.

It serves to *connect* those viscera having an incomplete or imperfect peritoneal covering with the *abdominal parietes*, and in such places,

supports a delicate anastomosis between the parietal and visceral vessels, as in the liver, kidneys, pancreas, duodenum, vertical parts of the colon, rectum, bladder, etc.

*Inflammations* may extend from these organs into this tissue where it readily spreads, usually in the direction of gravity. Thus an abscess from a neglected appendicitis may extend in the subperitoneal tissue of the iliac fossa to Poupart's ligament, where it may displace upward the parietal peritoneum and form a large abscess that can be opened without opening the peritoneum, as was done before the modern operation for appendicitis.

The *looseness* of this tissue allows the upward displacement of the parietal peritoneum just above the symphysis when a distended bladder rises out of the pelvis, and thus permits the extraperitoneal tapping or opening of the bladder. In front of the bladder it is rich in fat and forms the loose tissue of the "Cavum Retzii." At the upper end of the crural canal it forms the *septum crurale*, and it descends along the inguinal canal to form a delicate covering of the cord, the testis or a hernia. Its adipose tissue is the starting point of *subserous lipomata*, which may also push through small openings of the overlying parts, as in the linea alba, and simulate a hernia.

At the internal abdominal ring, especially on its inner side, this tissue contains a considerable amount of fat which, if it be absorbed or diminished from any cause, may leave a depression which favors the formation of hernia.

A rare form of *properitoneal hernia* may occur in this tissue, i. e., between the peritoneum and the transversalis fascia. The subperitoneal connective tissue forms a *perivascular sheath* for the large vessels which lie in it, and accompanies them outside the abdomen.

The *Parietal Peritoneum* is described later ; see p. 284.

#### Vessels and Nerves of the Anterior Abdominal Wall.

**Arteries.**—The *superficial arteries* (superficial epigastric and circumflex iliac) are branches of the femoral and lie between the layers of the superficial fascia. They are of little importance, although Verneuil has reported a case of bleeding from the superficial epigastric resulting fatally.

Of the deep arteries, the *deep epigastric*, a branch of the external iliac, is the most important. Where it reaches the anterior abdominal wall, just above Poupart's ligament, it lies behind the inguinal canal, just internal to the internal abdominal ring and a little above and to the outer side of the femoral ring. The vas deferens in the male, and the round ligament in the female, loop over it just internal to the internal ring and draw it slightly inward. Its *direction* may be marked off by a line, slightly curved inwards, from the outer end of the inner third of Poupart's ligament to a point an inch or so external to the umbilicus. In this line paracentesis should not be performed, for hemorrhage from this artery might be free in the loose tissue in which it lies inferiorly.

In its course it lies at first lateral to the rectus and then behind it. At first it is embedded in the subperitoneal connective tissue, then it pierces the transversalis fascia and, passing within the sheath of the rectus at the fold of Douglas, it lies behind the rectus, midway between its borders, and finally within the muscle where it anastomoses with the *superior epigastric branch* of the internal mammary artery.

Besides the latter artery, small branches derived from the two lower intercostals, the lumbar and the circumflex iliac arteries are found in the abdominal parietes. No artery of the antero-lateral abdominal parietes is of such size or importance as alone to contraindicate a given incision, but it is well to bear in mind the course of the deep epigastric artery and that it crosses the semilunar line.

**Veins.**—The *deep set* of veins are the paired *venae comites*, accompanying the deep arteries, in like manner with which they anastomose with one another as well as with a plexus in the parietal peritoneum and a *parumbilical vein* which, passing along the round ligament of the liver to that organ, connects the portal veins with the deep epigastric.

The subcutaneous or *superficial set* are single and do not exactly follow the corresponding arteries. The *superficial epigastric vein* is often seen through the skin. It *anastomoses* with the deep and the superior epigastric and thereby with the parumbilical and portal veins, and also with a subcutaneous vein (*v. thoracico-epigastrica*) which runs up the side of the thorax to join the axillary vein. This thoracico-epigastric vein may be continued independently into the femoral instead of or as well as joining the superficial epigastric.

The surface veins may become enormously dilated or *varicose*, to the size of the little finger, and so become very distinct. This condition (*caput medusæ*) usually depends upon their affording a *collateral circulation in obstruction* of the inferior cava or the portal veins, although this varicosity may exist without any such obstruction and, vice versa, the obstruction may exist without any varicosity.

Although it has been shown from the arrangement of valves that the *current* in these surface vessels above the navel is toward the axilla, and in those below, toward the groin, yet when the veins are dilated the valves become insufficient and the current can take an abnormal course. In portal obstruction the current in the superficial epigastric is toward the groin, where it empties into the femoral or the internal saphenous, and in caval obstruction the current is in the reverse direction and passes into the axillary through the thoracico-epigastric vein.

The direction of the current is determined by emptying the veins and allowing them to fill and is a point that may be utilized in diagnosis.

**Lymphatics.**—As to the *superficial lymphatics*, those above the level of the umbilicus go, with those of the breast, to the axillary nodes; those below this level, to the inguinal nodes.

Little is known of any *deep lymphatics*, but they probably accompany the vessels to the iliac and sternal glands.

**Nerves.**—The nerves supplying the antero-lateral abdominal wall are the lower thoracic nerves, and the iliohypogastric and ilioinguinal branches of the first lumbar nerve. The *sensory supply* of the skin is furnished by the anterior divisions of the lateral cutaneous branches and the anterior cutaneous branches of the lower seven thoracic nerves and by the hypogastric branch of the iliohypogastric nerve.

The sixth and seventh nerves supply the skin over the “pit of the stomach,” the eighth nerve corresponds to the middle linea transversa, the tenth to the umbilicus, the distribution of the twelfth (or subcostal) extends to within two inches of the symphysis, that of the iliohypogastric is below this.

The *muscles* of this region of the abdominal parietes are *supplied by* branches from the same nerves, with the exception of the sixth thoracic and the addition of a few filaments from the ilioinguinal nerve.

The *anterior portions* of these nerves *pass* between the transversalis and internal oblique muscles to the outer border of the sheath of the rectus, which they pierce to supply the muscle, within which they give off the anterior cutaneous branches. The fact that these numerous nerves supply the abdominal muscles, makes their position and direction of importance in planning incisions.

These nerves are placed at fairly *equal distances* apart, and *pass* downward and inward *in the lower third* of the ventral abdominal wall. (*i. e.*, the eleventh and twelfth thoracic, the iliohypogastric and the ilioinguinal nerves), nearly transversely inward *in the middle third* (*i. e.*, ninth and tenth thoracic nerves), and somewhat upward and inward *in the upper third* (*i. e.*, the seventh and eighth thoracic nerves).

According to Brewer the course of the *twelfth thoracic nerve* is indicated by a line from a point half an inch below the tip of the twelfth rib to the spine of the pubis on the opposite side; that of the *eleventh thoracic nerve* by a line from a point half an inch below the tip of the eleventh rib to the middle of Poupart's ligament on the opposite side, that of the *tenth thoracic nerve* from a point half an inch above the tip of the eleventh rib to the anterior superior spine of the opposite side. The line indicating the course of the *ninth nerve* is from a point just below the osteochondral junction of the ninth rib horizontally inward, that for the *eighth thoracic nerve* is from a point just below the outer end of the eighth cartilage horizontally inward to a point half an inch to the median side of the chondral border and then upward and inward parallel with the border and half an inch internal to it. In great abdominal distension or obesity these lines would not hold.

The lower nerves run somewhat more transversely than the fibers of the external oblique and its aponeurosis, so that they are in some danger of injury even by *oblique incisions* parallel to these fibers, as in operations for appendicitis, but they may be spared with a little care. *Vertical incisions* of any length, save in or near the median line, cannot avoid exposure and division of one or more of these nerves. Division of these nerves results in a paresis of that part of the abdominal muscles which is supplied by the nerves concerned, and this paresis

causes a weakness and bulging of the abdominal walls and increases the tendency to hernia. The direction of the nerves is nearly, if not quite, parallel to the cleavage lines of the skin.

An inflammation (*perineuritis*) of one or more of these nerves causes pain in the area of distribution, and may be accompanied or followed by a vesicular cutaneous eruption limited to the same area and known as *herpes zoster* ( $\zeta\omega\sigma\tau\gamma\rho$ —a girdle), or shingles. Pain or modified sensation (a sense of constriction or tightness) in the area of distribution may also be caused by pressure on the nerve trunk where it emerges from the spine, and is due to an injury or to the spinal caries of *Pott's disease*. Thus many cases have been recorded where a commencing Pott's disease has been mistaken or treated for "belly ache," or for trouble in the kidneys or bladder when the lower nerves are involved. The position of the spinal segment affected by disease or injury may be localized by the nerve or nerves involved.

The *lower thoracic nerves*, besides furnishing the motor and sensory nerve supply to the abdomen, also supply the intercostal muscles and costal pleurae. This accounts for the fact that the pain of a pleurisy near the base of the lung is often referred to the stomach by children, who seem to have less ability to locate pain than adults. The abdominal muscles are concerned with the intercostal muscles in the movements of respiration. The association of the sensory nerves of the abdomen with the motor nerves of the inspiratory muscles is illustrated by the violent inspiration or deep gasp given when cold water is thrown upon the belly. The lower ribs are fixed by the reflex contraction of the abdominal muscles so that this inspiration is confined to the upper ribs.

On account of the association in the same nerve of the sensory and motor fibers, the reflex contraction of the abdominal muscles occurs more rapidly than if these fibers were in separate nerves. The *sensory nerves* are thus enabled to do the duty of a *sentinel*, to give warning that can be immediately acted upon by the motor nerves by contracting the muscles. This is an important provision for, as we have already seen, the viscera are well protected from contusions only when the muscles are first contracted. The rapidity of the reflex contraction is well seen when a cold hand is laid upon the abdomen. Rigidity of the abdominal muscles is immediately caused so that satisfactory abdominal palpation cannot be practised unless the hands be warm.

A surface lesion like a burn, when rendered painful by exposure to the air, causes the abdominal walls to become rigid. Not only painful surface lesions but also painful visceral or deep lesions, like peritonitis, cause by reflex action a constant rigidity of the muscles so as to afford complete rest to the inflamed surfaces. The patient with peritonitis may also be unable to tolerate the least pressure, even of the bed clothes, such is the reflex sensitiveness of the skin.

The explanation of this reflex lies in the connection of the lower thoracic nerves, which supply the abdominal parietes, with the splanchnic nerves through the corresponding sympathetic ganglia. The

splanchnic nerves in turn go to the solar and other associated plexuses which provide the nerve supply of the abdominal viscera.

**Congenital Defects of the Abdomen.**—During *fetal life* the lateral abdominal walls grow and bend inward to meet and unite in the median line, which they do last of all at the umbilicus. In so-called *extroversion* (or *extrophy*) of the *bladder* this median union has failed in the lower part, where the base and posterior wall of the bladder, whose front wall is wanting, is thrust forward by the viscera beneath so as to appear at or in front of the level of the skin as a red area of mucous membrane, moistened by urine trickling from the visible opening of the ureters. This condition is usually associated with absence of the *symphysis pubis* and with *epispadias*.

Again, a failure of the parietes to unite mesially may result in a protrusion of the viscera, especially near the umbilicus, varying in size from a small *hernia* to one involving all the movable viscera. I have also seen a *congenital separation of the recti muscles* in a child (see p. 245).

**Injuries and Wounds of the Abdominal Wall.**—In *contusions* the fact should be remembered that *ecchymosis* may not occur even though the contusion be severe, and that when the muscles are contracted the viscera are likely to escape injury. A blow on the abdomen should never be considered trivial and refused treatment until after sufficient time has elapsed without symptoms to exclude the possibility of visceral injury. A *blow on the epigastrium* may be followed by *sudden death* without causing marks of parietal or visceral injury. The fatal result is probably due to an inhibitory action on the heart from a concussion of the solar plexus.

The important distinction in wounds of the abdomen is between *penetrating* and *non-penetrating wounds*. In the former the peritoneum is wounded and their seriousness depends upon *infection*, either from without or from a visceral wound, and upon *hemorrhage*. The subjacent viscera may escape injury because the weapon does not reach them or, in rare instances, the intestines may escape injury from a bullet or a weapon thrust among them.

If *infection* of an abdominal wound occurs, the loose connective tissue between the several layers and the space between the rectus and the rear wall of its sheath favor the spread of inflammation and of pus. The number of layers and the loose tissue between many of them makes it very easy, in probing a bullet or stab wound, for the probe to leave the track of the wound and pass between the layers of muscles or fasciæ. Hence probing such wounds is to be condemned.

On account of the different direction of the fibers of the several muscle layers their retraction in a wound or incision varies, so that an irregular wound results. The contraction of the muscles may favor the protrusion of the viscera through such a wound and, in replacing them, care should be taken not to push them into the spaces between the muscles or beneath the peritoneum. It is important and some-

times difficult to apply the sutures so that the cut edges of each of the muscular layers are in apposition, and unless this is done the strength of the wall is impaired. It is also of the utmost importance that the peritoneum on the two sides of the wound should be sutured so as to bring about its speedy union, otherwise a gap is left on its surface, which favors the formation of hernia at the site of the wound. The constant movement of the abdominal wall does not allow that rest which is so favorable or even essential to wound healing, but in spite of this most wounds heal well here.

### Operations and Incisions.

Operations are practised upon all the abdominal viscera, and for exploration or diagnosis. The *position of the incision* varies with the viscera to be approached. The *general rule* that the incision should give free access and avoid wounding nerves and large or important vessels is to be followed, but in addition the *danger of subsequent hernia* is to be considered. This danger is greater in the lower part of the abdomen, for here gravity adds to the protruding force of the intra-abdominal pressure, due to muscular action. Also, as Hyrtl says, aponeurosis is less resistant than muscle and a scar in the former is more likely to yield than one in the latter.

**Incisions** may be *directed* vertically, horizontally, or obliquely. *Vertical incisions* are most commonly practiced along the two fibrous or aponeurotic lines, the linea alba and the *linea semilunaris*. Through the latter line we may *expose* the appendix vermiciformis, the kidney, the gall-bladder and the bile-ducts; but the incision is objectionable because it divides nerves that supply a part of the rectus muscle, and the scar is in relatively thin fibrous tissue and is liable to yield and be followed by hernia.

Of course, in some cases, other considerations (greater safety, etc.) may outweigh the objections. The *danger of hernia* may be *obviated* by incising the sheath of the rectus muscle 1–2 cm. internal to its outer border, retracting the muscle inward and dividing the deep layer of the sheath in line with the incision of the superficial layer, thus forming a *trap-door incision*. In the upper part of the linea semilunaris the incision is not through fibrous tissue only, but we meet with the transverse fibers of the transversalis muscle, which here passes behind the rectus.

Of all *incisions* that in or near the *linea alba* is the most common. It is practised in most operations on the pelvic viscera, in most exploratory operations and in many others. The following *advantages* are claimed for incisions through the *linea alba*: (1) *Slight vascularity*; (2) *few important structures to be divided*; (3) *accessibility to all parts*.

1. The *slight vascularity* is a *disadvantage*, for it delays rapid and firm healing and so predisposes to hernia.
2. *Hernia* is also *favored by* the comparatively thin scar resulting

from the few blended structures to be divided, which also renders the incision more difficult, as it is hard to tell its exact depth at any given stage for want of landmarks. Moreover, if we have to extend the median incision past the umbilicus we encircle it, usually on the left because of the danger of wounding the parumbilical vein, sometimes of large size, which passes along the round ligament of the liver to the right of the median line. But as it is difficult to render the umbilicus aseptic there is danger of infecting the incision or the track of the sutures which unite this part of the incision. The above disadvantages of incisions in the linea alba are avoided and the advantages shared by an *incision through the rectus muscle* about an inch from the median line, separating bluntly the fibers of the muscle or retracting it outward in the manner of a trap-door. The lineæ transverse offer no serious obstacle to the vertical separation of the fibers of the rectus muscle.

In the epigastrium the *stomach* is *well exposed* by a vertical incision, which may be median or through the inner half of the rectus muscle, or by an oblique, a transverse, or an angular incision.

*Transverse or somewhat oblique incisions in the rectus* above the umbilicus are *not objectionable*, if properly united, for they only increase the number of lineæ transversæ and are not likely to wound the nerves. Below the umbilicus we should bear in mind the position of the deep epigastric artery in transverse section of the rectus.

The *transverse incision just above the pubes to expose the bladder* appears to me to offer little or no advantage over the vertical and, unless properly healed, it is likely to impair the function of the muscle as well as to lead to ventral hernia.

*In the area outside of the lineæ semilunares the best incisions* are those directed obliquely or transversely, parallel, or nearly parallel, with the cleavage lines of the skin and the direction of the nerves. Here the incisions are through a thicker muscular wall which, if properly united, affords more protection against hernia than those through thinner aponeurotic structures.

*In the lower half of this area* we commonly incise parallel to the fibers of the external oblique and its aponeurosis, *i. e.*, at right angles to a line joining the anterior superior iliac spine and the umbilicus. Separating the external oblique fibers we may reach the transversalis fascia by blunt separation of the internal oblique and transversalis muscles, which are practically in the same line. As this separation of the muscular layers is along different lines, according to the direction of their fibers, we do not get as much room from a given length of skin incision as if we incised the deeper muscles. The incision of the latter may be advisable if much room is needed; but the blunt *intermuscular incision* is an almost absolute safeguard against hernia, as the muscles come naturally together and close the wound when we cease to retract them. Moreover we can readily enlarge the intermuscular incision by incising the sheath of the rectus toward the median line and retracting the muscle in the same direction.

In the *upper part of this area*, an oblique incision nearly parallel with the costal margin is nearly in line with the nerves and cleavage lines of the skin, and gives a good exposure of the parts about the liver on the right side, the stomach or spleen on the left side.

To expose the liver, gall-bladder, etc., an oblique incision from a point below and external to the ensiform cartilage, one half inch or more to the inner side of the costal margin, to a point half an inch above the tip of the eleventh rib will only divide the ninth thoracic nerve. The same is true of a vertical incision through the outer part of the rectus muscle from a point half an inch below the lower border of the eighth costal cartilage to a point two inches above the umbilicus. For the same purpose Bevan's incision is serviceable, consisting of a vertical incision, along the outer border of the right rectus, whose lower end may be prolonged obliquely outward, near the level of the umbilicus, and whose upper end, three fourths inch below the costal margin, may be prolonged obliquely inward and upward by incising the sheath of the rectus and retracting the muscle. When much room is required for the safety of an operation the incision must be enlarged or added to where and in what way it is necessary, but in general the above considerations should apply.

### The Regions of the Abdomen.

The abdomen has been *arbitrarily divided* into *nine regions*, so that the viscera of these regions may be localized with reference to the surface area of these regions. Of course the relation of the viscera to the overlying surface is only approximate, for the position of the viscera has a wide range of physiological variation in different subjects or in the same subject at different times. This regional division may be of service in medical education, but in practice we determine the position of viscera by palpation, etc., and by reference to well-defined landmarks.

To aid the more precise description of the position of pathological or medicolegal findings the regions may be of more service. Unfortunately there is confusion and variation instead of uniformity in the boundaries of these nine regions.

The two vertical and the two horizontal planes which mark off these regions must be fixed with reference to landmarks easily located on the living body.

As usually described, the **vertical planes** pass through the middle of the inguinal (Poupart's) ligament, and nearly correspond with the lineaæ semilunares in the two upper zones. Hence they differ but little from the planes proposed along the outer border of the recti,<sup>1</sup> except in the lower zone, where the latter make the inguinal canal in the lateral regions, the former in the median region. The planes drawn vertical to the iliopectineal eminences<sup>2</sup> are objectionable because these

<sup>1</sup> Morris' Anatomy, 2d edition, 1898.

<sup>2</sup> Joessel ; Gray, American edition.

eminences cannot be easily enough located from the surface to serve as starting points.

The upper horizontal plane is best drawn as a *subcostal plane* connecting the lowest points of the tenth costal cartilages of each side. The ninth or eighth costal cartilages have been used by some, or the point where the vertical planes meet the costal margin.

The lower horizontal plane, as usually given, passes through the two *anterior superior iliac spines*. Some describe it as between the highest point of the iliac crests, others  $1\frac{1}{2}$  inches lower, through the point of the iliac crests most prominent laterally, or the *tuberculum cristæ*.

It is as important to know the viscera which are cut by these planes as the viscera in the areas bounded by them.

The vertical planes cut from below upward *on the right side*, the apex of the cæcum, small intestine, transverse colon, kidney, and gall-bladder (often); and *on the left side*, the sigmoid flexure, small intestine, kidney, transverse colon, pancreas, stomach, and spleen.

The upper horizontal plane passes through the second (or third) lumbar vertebra behind, and runs two inches above the umbilicus in front. The viscera cut by it are the stomach, transverse, ascending and descending colons, duodenum (lower curve), both kidneys and the small intestine.

The lower horizontal plane (interspinous) passes at about the level of the top of the sacral promontory and cuts the cæcum, small intestine and sigmoid flexure. The names and visceral contents of the nine regions marked off by the above planes may be seen in the following table. The adjacent parts of the lower iliac and hypogastric regions form the *inguinal region*.

Right.	Middle.	Left.
R. Hypochondriac.	Epigastric.	L. Hypochondriac.
<i>Liver</i> , greater part of right lobe. <i>Gall-bladder</i> , part of fundus (sometimes). <i>Kidney</i> , upper and outer part. <i>Colon</i> , hepatic flexure and part of ascending colon.	<i>Liver</i> , whole or greater part of left lobe, part of right lobe. Most or all of <i>gall-bladder</i> . <i>Stomach</i> , middle and pyloric regions, both orifices. <i>Intestines</i> ; <i>duodenum</i> , first and second portions and end of third portion. <i>Small intestine</i> . <i>Transverse colon</i> (part of). <i>Pancreas</i> , head and body; <i>Spleen</i> , upper and inner part. <i>Kidneys</i> , upper and inner part. <i>Adrenals</i> .	<i>Liver</i> , sometimes part of left lobe; <i>Stomach</i> , fundus; <i>Spleen</i> , greater part; <i>Pancreas</i> , tail; <i>Kidney</i> , upper and outer part; <i>Colon</i> , splenic flexure, and part of descending colon.

**Horizontal Plane at Level of Lowest Point of the Tenth Costal Cartilages.**

Right Lumbar.	Umbilical.	Left Lumbar.
<i>Kidney, lower and outer part; Intestine; ascending colon; cæcum (part of); vermiform appendix (often); part of ileum and its termination.</i>	<i>Kidneys, lower and inner portion with ureters; Intestine, third part duodenum; part of jejunum and ileum; greater part of transverse colon; part of sigmoid flexure.</i>	<i>Kidney, lower and outer part; Intestine, jejunum; part of descending colon; part of sigmoid flexure.</i>

**Horizontal Plane at Level of Anterior Superior Iliac Spines.**

Right Iliac.	Hypogastric.	Left Iliac.
<i>Intestine; ileum, part of. Cæcum, lower part of. Vermiform appendix.</i>	<i>Intestine, small Intestines; part of sigmoid flexure; upper part of rectum; tip of cæcum, usually; vermiform appendix (often). Bladder in children and, when distended, in adults. Uterus, fundus and appendages.</i>	<i>Intestine; small Intestine; part of sigmoid flexure.</i>

**The Umbilicus and Umbilical Hernia.**

In early foetal life there pass through the umbilical opening, which is bordered by fibers of the linea alba, the urachus, the umbilical arteries and vein and a loop of small intestine. Outside of the body these are bound together by embryonic tissue (Wharton's jelly) and covered with amnion to form the umbilical cord. Later the intestinal loop retracts within the abdomen, leaving in the cord, for a time, the vitello-intestinal duct which connects the end of the loop with the yolk sac. The proximal end of this duct may persist as a finger-like process, *Meckel's diverticulum*, connected with the lower end of the ileum, from one to three feet from the ileocecal valve.

Occasionally, from imperfect development, the foetal condition persists at birth, and a loop of intestine or an intestinal diverticulum projects a variable distance through the umbilical ring into the cord. This constitutes a congenital umbilical hernia. If care is not exercised in tying the cord this projection may be tied or cut off causing a *faecal fistula*, which may be preceded by obstruction if an intestinal loop is tied. Two or more cases of such an accident are on record. More rarely the hernial protrusion is larger and contains a larger mass of intestine or other viscera with a thin covering.

At birth the cord is tied a short distance from the belly wall and

the proximal end shrivels, dries up and in about five days *drops off at the same spot in all cases*, i. e., the level of the abdomen, no matter where the ligature is applied. This is accounted for by the sphincter-like arrangement of elastic fibers around the umbilicus (especially on its deep aspect), which contract and shut off like a ligature the vessels passing through the ring, including those supplying the cord itself.

At birth and for some time afterward a *distinct ring* can be *felt at the umbilicus*. At the spot where the stump of the cord separates from the belly wall a *scar* forms which binds together the stumps of the umbilical vessels. The skin rapidly grows over this scar which, when it contracts, throws the skin into folds forming the *umbilical papilla*. It is on account of the creases between the folds that it is so difficult to make the umbilicus aseptic before operation.

As we *look at this scar from behind* we see the converging empty umbilical arteries and the median urachus running to it from below, and the empty umbilical vein running upward from it. At first there is a slight depression in the center of the contracting ring, into which there is a little projection of peritoneum. During infancy a hernia may protrude through the not yet firm cicatrix in the still open ring, between the arteries and the vein, or at a later period above them. This is known as *infantile umbilical hernia*. It occurs in the first few months of infancy and is due to frequent coughing, crying, or straining on account of constipation, phimosis, etc. If properly *treated* by being kept reduced it usually heals without operation, for the cicatrical contraction of the ring can then go on to final closure.

The umbilical vessels having become obliterated and reduced to fibrous cords in the first month of infant life, the abdomen grows more rapidly than these obliterated vessels, which therefore pull upon the umbilical cicatrix. The traction of the two obliterated arteries and the urachus is stronger than that of the vein, so that the fibrous cords representing all three vessels are pulled down to the lower margin of the umbilicus. The upper half of the scar is thin while the vessel cicatrix, in the lower half, becomes the strongest part of the umbilicus and the latter the strongest point in the abdominal wall. Consequently in adult life an *acquired umbilical hernia* either protrudes through the upper part of the reopened ring or altogether above it, and is in reality a hernia of the linea alba, on the lower aspect of which appears the umbilical cicatrix.

On the deep aspect of the umbilicus in about two thirds of the cases examined,<sup>1</sup> are seen transverse fibers passing from the inner border of one rectus sheath to that of the other. They are known as the *fascia umbilicalis*, are adherent to the peritoneum, cover the deep surface of the umbilical vein and represent a thickening of the transversalis fascia. In certain cases it is present only above and below the umbilicus, leaving the latter free and theoretically more exposed to hernia. But as acquired hernia occurs uniformly above the umbilicus the common arrangement, where the fascia ends by a free margin

<sup>1</sup>Sachs (Virch. Arch., Bd. 107).

a little above the cicatrix, may be equally favorable to hernia formation.

Richel<sup>1</sup> likened a canal-like space above the umbilicus, between the linea alba and this fascia, to the inguinal canal in relation to hernia formation. But the analogy is purely an imaginary one.

The *umbilical papilla*, or cutaneous cicatrix proper, is at the bottom of a depression which is due to a lack of subcutaneous fat immediately about it. It corresponds to the original fibrous ring of the umbilicus, derived from the tissues of the linea alba. The layers of the abdomen in this cicatricial area, *i. e.*, skin, aponeurotic scar tissue, fascia transversalis and peritoneum, are so thin and closely adherent that, when stretched out by a hernia, we can hardly avoid opening the peritoneal sac, unless by incising well above, below, or laterally. The superficial fascia is practically wanting.

In congenital and many infantile herniæ the omentum is not found in the sac, for at this period it has not developed as low as this. In the acquired form it is nearly always present and adherent.

**Coverings of Umbilical Herniæ.**—Congenital herniæ, embryonic tissue of the cord and an amniotic layer continuous with the skin at the ring. There is no true sac.

Infantile herniæ, peritoneum, forming the sac, transversalis fascia, skin. (The superficial fascia is so scanty as to be practically wanting.)

Acquired herniæ, the same as the infantile variety with the addition of the superficial fascia and the aponeurotic tissue of the linea alba, for the hernia is really through the linea alba above the scar.

The *subperitoneal tissue* is so small in amount as to be omitted, for the peritoneum is here very adherent to the fascia.

In foetal life the *urachus*, *derived* like the bladder from the stalk of the allantois, has a *lumen* connected with that of the bladder, etc. According to Luschka, a total obliteration of the lumen of the urachus is not the rule, but an unobiterated part is usually found. This may be connected with the bladder or shut off from it. Occasionally such a patent portion opens as a *fistula at the umbilicus*. A probe passes a variable distance down the urachus and a sero-mucous secretion, not urine, is discharged from the opening of the fistula. I have met with a few such cases, which are readily closed by scraping and cauterization.

A few cases are on record where the foetal *canal of the urachus* has *remained open* from the bladder to the umbilicus, so that on micturition the urine would stream from the latter when its passage through the urethra was impeded. In case of stricture of the urethra its function could be performed by such a urachus.

Another abnormal condition observed is a *reopening of the urachus* during retention of urine, thus allowing urine to escape at the navel and relieve the retention. But, as Hyrtl suggests, it is not unlikely that in such a case the urachus was patent as far as the umbilicus. *Urinary calculi* have also been found in the *urachus*, where the latter

<sup>1</sup> Anat. Chirurgicale, 5th ed., p. 745.

connected with the bladder, and in one case a stone was removed from the bladder by the aid of a finger passed through a patent urachus.

### The Inguinal Region and Inguinal Hernia.

The boundaries of this region are Poupart's ligament below, a horizontal line from the anterior superior iliac spine above, and internally the median line or, for practical purposes, the outer border of the rectus muscle. The several layers of the belly wall are essentially the same here as elsewhere anteriorly, except that (1) the *intercolumnar fibers and fascia* are closely joined to the outer surface of the external oblique aponeurosis and (2) the *conjoined tendon*, representing the internal oblique and transversalis muscles, arches over from the outer half of Poupart's ligament to the iliopectineal line and the pubic crest. This leaves bare of these muscles the inner half of the ligament and a narrow semilunar space above it, corresponding to the inner two thirds of the inguinal canal.

**Superficial inguinal lymphatic nodes**, eight to ten in number, are found between the superficial and deep layers of the superficial fascia in two sets, an *oblique set* along and just above Poupart's ligament, and a *vertical set* over and about the saphenous opening. The *internal group* of the oblique or inguinal set receives the lymphatics from the external genitals, distal part of the urethra, perineum, and the inner part of the buttock; the *middle group* those from the abdominal parietes below the umbilicus, the *external group* those from the outer part of the buttock and the lower part of the back. These become enlarged from cancerous, syphilitic and suppurative affections of these regions, and we can often tell the part affected by the nodes first involved.

Their efferent vessels pass through the cribriform or the deep fascia to reach the deep inguinal or the external iliac nodes. The commonest cause of enlargement of these nodes is venereal disease, but enlargement may occur here without visible local lesion, as with the cervical lymph nodes.

What gives this region its importance is the presence of the **inguinal canal**, an *oblique passage* way through the abdominal wall for the spermatic cord in the male and the round ligament in the female. This canal, like many others in the body, is not an actual but a *potential canal*, a breach or track forming a *weak spot* in the abdominal wall along which a body may be thrust. An open canal is a pathological condition due to hernia.

The **inguinal canal** in the male is *formed by* the passage of the processus vaginalis and the testis through the abdominal wall, which then closes down snugly on the spermatic cord, which follows the testis.

It should be remembered that the *testis*, etc., does not break through each layer as a bullet through a board, but *pushes before it the several layers* which are stretched out to form a laminated covering of the testis and cord.

The **peritoneum** forms an exception to the statement that the layers of the abdominal parietes are pushed before the testes, etc. The peri-

tonium is the first structure to pass out through the inguinal canal as the *processus vaginalis*. The testis is from the outset outside of the peritoneum, having developed behind it, so that it need not and cannot push it as a pouch before it, but descends alongside of and outside of the processus vaginalis through the inguinal canal and so into the scrotum. (See scrotum and testes.)

The two ends or openings of the canal are called the *abdominal rings*. The inferior and mesial one is known as the *external ring* because it is superficial, though more internal or mesial than the internal ring.

The **external or superficial abdominal ring** is where the cord, or round ligament, passes through the aponeurosis of the external oblique and spreads apart two fasciculi of this aponeurosis called *pillars of the ring*. A triangular gap is thus formed with its base downward and inward over the spine and outer part of the crest of the os pubis. The lower and outer fasciculus or "pillar" of the ring blends with and in fact is the inguinal (Poupart's) ligament. It is attached to the pubic spine internally and the fascia lata below. It is the stronger and more posterior pillar, and on it rests the cord or round ligament. The upper and inner "pillar" is attached to the pubic crest. So-called **intercolumnar fibers**, passing upwards and inwards from the outer half of Poupart's ligament, bridge across the outer angle where the two pillars meet, round off this angle and bind securely together the fibers of the two pillars so as to prevent their further separation. These intercolumnar fibers are joined together by a thin membrane into a fascia, the *intercolumnar fascia*, which is attached to the margins of the pillars, and is prolonged over the cord and testes as the *external spermatic fascia*. It represents the covering furnished by the external oblique aponeurosis.

The base of the triangular gap is rounded off by the **triangular ligament**, lying at a deeper level than the ring, and sometimes known as the posterior pillar. Thus the *external ring* is *oval* with its long diameter obliquely vertical. It lies one inch (2-3 cm.) from the median line, above and internal to the pubic spine, and can readily be felt by invaginating the scrotum with the finger and following up the front of the cord.

It averages one inch by one half inch though its size is very variable and it is smaller in the female than in the male. In cases of non-descent of the testis, or after its removal, the external ring may be narrowed or obliterated. Normally it will admit the tip of the index finger. It is felt to be *enlarged in flexion, adduction and inward rotation of the thigh by means of the relaxation of the fascia lata and thereby of Poupart's ligament, the external pillar, which is attached to this fascia. Hence the thigh is placed in this position for taxis or for examination of the canal, also to see if a truss or bandage fits snugly enough to retain a hernia. Vice versa it is narrowed in extension, abduction and outward rotation of the thigh by the traction of the fascia lata making tense the external oblique aponeurosis. This position is one which may be employed after operations for hernia.*

**The internal or deep abdominal ring** is where the cord passes through the *transversalis fascia*, which is here called the infundibuliform fascia because it has formed a funnel-shaped pouch for the testis and still presents a slight pit or depression. The inner fascial margin of this depression forms a prominent crescentic edge, due to the traction of the vas deferens as it bends inward and downward into the canal.

This ring lies about half an inch above Poupart's ligament at a point slightly internal to its center. It is oval in shape with its long diameter directed vertically. The *transversalis fascia* is not broken through by the passage of the testis or the round ligament but is carried down with them as an enveloping pouch, the *infundibuliform or internal spermatic fascia*, whose upper opening, the *internal ring*, is closed around the cord or round ligament.

**The inguinal canal**, extending obliquely between these two rings, measures  $1\frac{1}{2}$  inches in length in the male and two inches in the female. Its direction is somewhat more vertical than Poupart's ligament, and its obliquity serves as a valve to lessen the chance of a hernia entering it. Its size varies with that of the cord or round ligament which occupies it, hence it is smaller in the female. The right canal averages larger than the left, a fact that may help to explain the preponderance of hernia on the right side.

**Walls of the Canal.** (Fig. 65.)—*In front* lie the aponeurosis of the external oblique and, in the outer third, the lower fleshy fibers of the conjoined tendon. These same fibers arch above it. *Behind* lie the transversalis fascia and, opposite the inner half of the external ring, the conjoined tendon and the triangular ligament. *Above* it is the conjoined tendon, *below* is the gutter formed by the junction of Poupart's ligament and the transversalis fascia, above which lies the cord at a distance which increases, as we proceed outward, to  $\frac{1}{2}$  inch at the internal ring. This fact is important in opening iliac abscesses or exposing the external iliac artery, in this space.

Fat is abundant in the *subperitoneal tissue* behind the rear wall of the canal, so that masses of fat are commonly found adherent to the outside of the neck of a hernial sac, especially on its mesial side.

Lying in this subperitoneal tissue are the **deep epigastric vessels**, structures of great practical importance, which pass *behind the canal just internal to the internal ring*. Between the internal ring and these vessels the transversalis fascia is very strong; internal to the vessels, where a direct hernia makes its way forward, it is much weaker. Besides the front walls of the canal as above given, other tissue layers, derived from the layers of the abdominal wall, form the *coverings of the spermatic cord or of a hernia*. Thus the infundibuliform portion of the transversalis fascia is prolonged down the canal as a tubular covering of the cord, etc. As the testis passes beneath the lower fibers of the internal oblique, in the conjoined tendon, these fibers are pulled down and spread out in front and at the sides of the cord or a hernia, as the *cremasteric muscle and fascia*. Occasionally the testis passes between

PLATE XXXI.

Sagittal section of anterior abdominal wall through the middle of the inguinal canal. (Tillaux.)

PLATE XXXIII.

FIG. 66.

Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)

instead of beneath these fibers, in which case the cremaster is found behind as well as in front and at the sides of the cord, etc.

**Inguinal hernia** is the passage of one or more of the abdominal viscera through, or partly through, the abdominal wall, following in whole or in part the inguinal canal. When *complete*, it emerges at the external ring. There are two principal groups of inguinal herniae according as the point at which they pass through the transversalis fascia lies *external or internal to the deep epigastric artery*.

**Inguinal Fossæ.** (Fig. 66.)—As we look at the peritoneal surface of the abdominal wall in the inguinal region we see on each side two longitudinal ridges or folds of the peritoneum, which converge as they ascend toward the umbilicus where they meet a median fold, due to the urachus raising up the peritoneum. The most lateral fold is the *plica epigastrica*, a fold of peritoneum elevated by the deep epigastric artery and forming the lateral boundary of *Hesselbach's triangle*. Somewhat nearer the middle line is the *plica hypogastrica*, due to the obliterated hypogastric artery.

In the inguinal region these elevated folds mark off certain *depressions or fossæ*. External to the epigastric fold is the *external inguinal fossa*, at the bottom of which we see a funnel-shaped depression of the peritoneum, which corresponds to the internal abdominal ring. Through the peritoneum we can usually see the vas deferens, coming from within and looping around the epigastric artery to enter the ring, where it joins the spermatic vessels coming from above. Between the epigastric and hypogastric folds is the *middle inguinal fossa*, which corresponds to the rear wall of the inguinal canal as far as the outer half of the external ring, and is formed by the weaker part of the transversalis fascia. Between the hypogastric fold and the outer border of the rectus muscle is the *internal inguinal fossa*, corresponding to the inner half of the external ring.

When a *hernia* pushes through in the external fossa we call it an *external, indirect or oblique inguinal hernia*; when in the middle or internal fossa, it is known as an *internal or direct inguinal hernia*. These two primary varieties of inguinal hernia are named internal and external with reference to the relation of the neck of their sacs to the deep epigastric artery, and direct and indirect or oblique with reference to their straight or oblique course through the parietes. The resistance of the abdominal wall is less at these fossæ than elsewhere.

**External, Indirect or Oblique Inguinal Hernia.**—This follows the course of the *inguinal canal*. An *incomplete hernia*, or one not passing beyond or only just beyond the external ring, is called a *bubonocele* from the bubo-like swelling. A *complete hernia* sooner or later descends into the scrotum and is called *scrotal*. At the external ring, as in the canal, it lies in front and slightly to the outer side of the cord which it follows to the scrotum. The *coverings* of such a hernia are the same as those of the cord in the same situation, *i. e.*, skin, superficial fascia, intercolumnar fascia (also called external spermatic fascia), cremasteric fascia, infundibuliform fascia (sometimes called internal spermatic

fascia). The last three layers form what is sometimes known as the *fascia propria*, a term of no great importance. The serous sac is derived from the peritoneum at the bottom of the external fossa, and is separated from the fascial layer by subserous tissue.

These herniae are *pear-shaped*, with the small end above, at the narrow oblique neck in the canal. The *contents* are not characteristic; almost any of the lower movable viscera may be within the sac. Small intestine is commonly found, omentum often, and the latter is apt to adhere to the sac and make the contents irreducible. Not infrequently, especially in congenital herniae, the cæcum and vermiform appendix are found in herniae on the right side.

Despite the long and oblique course of the neck of *external inguinal herniae*, in a canal whose muscular walls would naturally tend to close it, and despite the more direct course of *internal inguinal herniae* through an anatomically weaker part of the abdominal wall, the former occur *much more commonly*. They are especially *common in early life* and this fact, as well as their greater frequency, is to be *explained in great measure by congenital conditions*. In foetal life one ring lies in front of the other, to facilitate the passage of the testes, so there is scarcely any canal. In early childhood the inguinal canal passes more directly and less obliquely through the abdominal wall than in the adult, a fact which favors the formation of herniae. The adult obliquity of the canal is acquired only after the development of the pelvis is completed.

Preceding the descent of the testis from the region of the kidney into the scrotum a pouch of peritoneum, the *processus vaginalis*, descends through the abdominal wall where the canal is to be, and reaches the scrotum where it is to form the tunica vaginalis testis. After the testis has reached the scrotum, in the eighth month of foetal life, the neck and upper part of the pouch, down to the upper end of the epididymis, tend to become closed. It is normally reduced to a small cord of fibrous tissue, lying among the elements of the cord, which is attached to the bottom of the funnel-shaped depression of peritoneum in the external fossa. This *closure proceeds usually from two points*, the internal ring and just above the epididymis, commencing as a rule at the former point. Part of the pouch between these two points may remain open and give rise to an "*encysted hydrocele of the cord*," if fluid collects in it.

**Varieties of External Oblique Inguinal Hernia due to Congenital Defects in the "Vaginal Process."**—1. Sometimes the vaginal process does not close but remains continuous with the peritoneal cavity. A hernia may descend into this process as a *sac* which is *performed or congenital*. Hence this variety is known as **congenital inguinal hernia**. Such a hernia need not occur at once or even shortly after birth. It may develop after some years, in which case the upper opening of the process, remaining constricted or closed by a thin septum, is dilated or torn by the hernia forced through it by some sudden strain. It may even occur when the testis has not descended, pro-

vided the processus vaginalis has passed into the scrotum. In congenital herniae the *sac* is very *thin*, the *neck* long and *narrow*, and the parts about it have been little disturbed or distended so that *strangulation* is relatively *more frequent* and severe in this variety than in the acquired form. Reduction by *taxis* may be *difficult* by reason of its long narrow neck. As the natural tendency of a congenital sac is to close during early life, especially as the canal grows longer and more oblique, we can often effect a cure in children by keeping the contents permanently reduced.

FIG. 68.

Diagrammatic representation of the varieties of external inguinal hernia due to congenital defects in the vaginal process. 1, the processus vaginalis showing the two points where closure of the upper part commences, at C and C'; 2, congenital hernia; 3, hernia into the funicular process; 4, infantile hernia; 5, acquired hernia. E, external abdominal ring; I, internal abdominal ring; P.S., peritoneal sac; B, herniated bowel; F.P., funicular process; T, testis.

2. The upper end of the vaginal process may close while the rest remains open, a condition which is the rule in early infancy. If under such circumstances a hernia with its peritoneal *sac* is forced down or, according to Lockwood's theory, a peritoneal *sac* is drawn down by the gubernaculum, such a hernia is called an **infantile inguinal hernia**, for it was first described in infants.

As the *sac* lies behind the open vaginal process we must pass through the process to open the *sac*, and in so doing we would *divide three layers of peritoneum*, two of the process and one of the *sac*. The variety is uncommon and unimportant. The hernial *sac* may occasionally project into or invaginate the vaginal process, giving rise to the term **encysted hernia**.

3. Again the closure of the vaginal process may occur only below, just above the testis, and a hernia into this preformed *sac* is known as a **hernia into the funicular process**.

This *sac* is *congenital* and it differs from the so-called congenital hernia only in the fact that in the latter the contents are in contact with the testicle, in the former they are separated by the septum which has shut off the testicular pouch. Herniae which become fully formed in a short time are of congenital origin.

4. Finally those herniae whose *sac* is formed anew from the peritoneum of the external fossa are known as **acquired external inguinal herniae**. This variety *develops more slowly* and does not descend as low

in the scrotum or come in such close contact with the testis as the congenital varieties.

**Internal or direct inguinal hernia** is one which *emerges* internal to the deep epigastric vessels and, as its name implies, *passes* directly forward through the abdominal wall where it appears to be weakest. Nevertheless it is far *less common* than the indirect form, a fact *due to* congenital conditions, the presence of the cord in the canal and the funnel-shaped depression of peritoneum at the internal ring which act as predisposing causes of the indirect variety. Direct hernia *occurs most often* when the abdominal walls have lost their strength and are lax, as in old age, after any prolonged distension, or after emaciation following obesity. Its *point of entry* is usually in the *middle inguinal fossa* opposite the external ring, *rarely* in the *internal fossa*, in which case it has been called "*internal oblique hernia*" as its course is somewhat obliquely outward to emerge at the external ring. The *neck* of a direct hernia is usually *wide*, admitting one or two fingers, so that the pulsation of the deep epigastric artery can be readily felt to its outer side and *strangulation* is *not common*, occurring most often at the external ring. Its *coverings* differ only nominally from those of the external variety. *Transversalis fascia* takes the place of that local subdivision of it, the infundibuliform fascia. In place of the cremasteric fascia we have the *conjoined tendon*, except in certain cases where the hernia escapes beneath or breaks through between its fibers without receiving a covering. If it escapes through the inner fossa the *triangular ligament* may form one of its coverings.

Other features of this form of hernia may be best brought out by observing the **differences between internal and external inguinal hernia.**

The *shape* of an internal inguinal hernia is globular on account of its short neck, that of an external is pear-shaped.

The *size* of the former is smaller and it has little tendency like the latter to follow the cord or descend low into the scrotum. The *position* of the former is more internal, and it lies more internal to and in front of the cord instead of in front of and external to it. On reduction the *track of the neck* of the internal is short and straight, that of the external is oblique and longer. Also if the finger can be introduced to their deep openings, the *pulsations of the deep epigastric artery* may be felt internally in external hernia and externally in internal hernia; while internally in the latter may be felt the edge of the rectus muscle.

The external form is often congenital, the internal never. The external form occurs especially in early life, the internal late in life.

From these differences it would seem an easy matter to *distinguish between the two forms*, and so it is where the relations of the various parts are not much disturbed, as in recent or congenital herniæ. But in *old external inguinal herniæ* the traction of an increasing weight on the inner side of the internal ring enlarges it on its internal aspect and so *shortens the canal* and makes it *less oblique*. Also if the rupture is

irreducible some of the diagnostic points will be wanting. Thus it may be difficult or impossible to distinguish between the two varieties.

**Hernia Operations.**—The *incision* over the course of the canal, and for a short distance internal to it, is laid out according to the landmarks we have given for the canal, and the visible or palpable position of the hernia. The superficial external pudic artery is usually divided but is of no importance. Several large veins, varying in size and number, may be met with crossing the line of incision. In recent or small external herniae the point of constriction, if strangulation occurs, may be at the internal or external ring, but it is more often in the narrow neck of the sac itself, which must then be opened.

In the operation most often practised, that of Bassini, the dilated or enlarged canal is obliterated, so as not to leave an easy passage way for the recurrence of the hernia, and a new track is made for the cord.

**How are We to Recognize the Different Layers?**—It is neither necessary or always possible to distinguish all of them. After division of the skin whatever moves with the cut edges belongs to the superficial fascia, unless inflammation has rendered the latter adherent to the parts beneath. The external oblique aponeurosis can easily be told by its pearly shining oblique fibers. The cremaster or conjoined tendon is the only muscle divided, and hence may be recognized. Some difficulty may be found in determining whether the peritoneal sac has been opened or not.

In congenital inguinal herniae the sac is closely adherent to the fascial layer outside. This may enable us to know when we meet with such a hernia, but it makes it more difficult to free the sac as well as to know when we have opened it.

*How are we to distinguish between the sac and the intestinal wall?*

1. The outside of the sac has not a shiny smooth surface, like that of the peritoneal surface of the intestine, but often shows attached to it little lumps of fat belonging to the subperitoneal tissue.

2. The vessels on the sac run more vertically, those on the intestine, circularly.

3. If we pinch up a fold between the fingers the sac is *very thin*, the intestinal wall thicker. The presence of *fluid* within the sac, in large amount in strangulated hernia, is also of great diagnostic importance.

**In what direction should we not incise to relieve a constriction of the neck of an inguinal hernia?** In the *external form*, not backwards on account of the cord, nor inwards on account of the deep epigastric artery. In the *internal form*, not backwards on account of the vas deferens and blood vessels, nor outwards for fear of the deep epigastric artery. But as it is often impossible to distinguish between the two forms it is advisable in any case to incise as if it might be either variety, and not to cut backward, inward, or outward.

**Hence we should incise upward or upward and slightly inward, i. e., parallel with the deep epigastric artery.** An extensive cut is unnecessary, several small cuts answer equally well.

**The Length of the Mesentery in its Relation to the Formation of the Hernia.**—Mr. Lockwood has shown : (1) That with a *mesentery of normal length* the intestine may be drawn down through the external ring but not into the scrotum. (2) That the mesentery is *relatively longer in infancy*, decreasing rapidly in the second year, and averaging eight inches in length in the adult. In the congenital herniae of infancy the mesentery may allow the gut to descend into the scrotum without first becoming lengthened, as is necessary in adults.

**An interstitial inguinal hernia** is one *into* and not through the *belly wall*. It usually starts as an external hernia but instead of passing out through the external ring it makes its way between some of the layers of the abdominal wall. This form of hernia is most *apt to occur when*, for some reason, the *external ring is narrower* than normal or is closed. These conditions are present when the testicle has not completely descended but is lodged just above or within the inguinal canal. The latter position of the testis most favors the production of such a hernia, for the upper end of the canal is enlarged and commonly occupied by a pouch of peritoneum.

In such a hernia the tumor is flattened out. According to Tillaux, strangulation may occur by compression of the surrounding muscular layers, and taxis is more harmful than useful.

**Reduction en Masse.**—A hernia may be reduced by taxis together with its sac so that any constriction in the neck of the sac still exists. In such cases the sac may be pushed up between the peritoneum and the abdominal walls or, if the infundibuliform covering is ruptured, in front of or behind the conjoined tendon which forms the upper boundary of the canal.

**Inguinal Hernia in the Female.**—A pouch of peritoneum, the *canal of Nuck*, corresponding to the vaginal process of the male, descends in foetal life for some distance along the round ligament and when, as sometimes happens, it remains open it may *form the sac of a congenital hernia*.

Inguinal hernia in the female is *most common* in infancy, early childhood or after the first pregnancy. In the former case it is congenital, in the latter acquired, the canal having become distended during pregnancy by the enlargement of the cord, which shrivels after childbirth but leaves the canal more lax. The round ligament bears the same relation to the hernial sac as does the cord in the male.

After emerging at the external ring a hernia may pass down into the labium majus. The *coverings* are the same as in the male except that the cremasteric layer is wanting. The *contents* are also the same except that the ovary or even the uterus, in part, may be found in the sac. Internal inguinal hernia is very rare in women.

**Operations in this region**, except for hernia, are chiefly those to shorten the round ligaments, to open abscesses, or to tie the external iliac artery. To *shorten the round ligament* the *incision* is made as for hernia or a little more horizontally. The external ring is exposed, the tissue lying just internal to it is hooked up with a blunt hook and

the round ligament is sought for in this tissue. If the ligament can not be so found, the canal should be slit up and its contents caught up on the hook. After pulling it down for a certain distance, the ligament becoming more fleshy and thick, a double sheath of peritoneum is drawn down with it. The latter may predispose to subsequent hernia.

**Abscesses** are principally of two varieties, to be spoken of in the study of the iliac fossa. One variety is in the subperitoneal tissue of the iliac fossa and is limited inferiorly by the line of Poupart's ligament. Here it raises up the peritoneum and may be incised, just above Poupart's ligament, without opening the peritoneum. The other, psoas abscess, is beneath the iliac fascia and may point above or below the middle or outer half of Poupart's ligament. When above the ligament it may be exposed and opened after incising the transversalis fascia and pushing up the lower limit of the peritoneum, thus bringing to view the iliac fascia.

We proceed in a similar way to expose the external iliac artery, for which see Iliac Region, p. 276.

### The Inguino-femoral Region and Femoral Hernia.

This region is the *passage way* between the upper part of the thigh and the region above. *Poupart's ligament* bridges across the concave iliopubic margin of the hip bone and thereby forms a space, mainly occupied by the iliopsoas muscle and the external iliac vessels in passing into the thigh. The fascia investing these structures subdivides the space into compartments or lacunæ.

The largest and most external of these is the muscular compartment occupied by the iliopsoas muscle and the anterior crural and external cutaneous nerves. It is bounded externally and behind by the bony iliac margin between the anterior superior spine and the iliopectineal eminence; in front by Poupart's ligament, and internally by the iliac fascia. This fascia is firmly attached to the transversalis fascia and Poupart's ligament along the outer 4 cm. of the latter, but then separates from them to pass to the iliopectineal eminence, where it is continuous with the pectineal fascia, i. e., the pubic portion of the fascia lata. It is in this compartment that a *psoas abscess* passes beneath Poupart's ligament to "point" below it.

The *pectineus muscle* passes up a short distance above Poupart's ligament and may be said to occupy a *pectineal compartment*, limited behind by the horizontal pubic ramus and in front by the pectineal fascia. The upper limit of this fascia, along the iliopectineal line, is thickened by transverse fibers from Gimbernat's ligament to form what is known as *Cooper's ligament*.

The rest of the space is triangular in shape and, save the inner angle occupied by Gimbernat's ligament, constitutes the *vascular compartment*.

This is bounded in front by Poupart's ligament (i. e., the superficial femoral arch) and the transversalis fascia, attached to Poupart's liga-

ment, which is thickened by transverse fibers and known as the *deep femoral arch*. Behind the compartment are the iliac and pectineal fasciae, continuous with one another. The external iliac vessels and the crural branch of the genitocrural nerve *occupy* this compartment in their passage into the thigh, the vein lying internal to the artery.

The vessels do not occupy the entire compartment, but there is an interval of 3/5–1 inch between the vein and the outer margin of Gimbernat's ligament, which constitutes the **femoral ring**, through which a femoral hernia forces its way beneath Poupart's ligament.

In passing beneath Poupart's ligament into the thigh to become the femoral vessels the *external iliac vessels* carry with them a fascial sheath, the **femoral sheath**, which bounds the vascular compartment and is continuous with the fascia lining the abdomen, *i. e.*, the *transversalis fascia* in front and the iliac fascia behind. These fasciae are continuous with one another internally and externally so as to form a complete sheath. This sheath is *funnel-shaped*, wide above but closely embracing the vessels below, where it is continuous with their proper sheath. The width of the sheath beneath Poupart's ligament prevents compression of the vein and pinching or stretching of the vessels in movements at the hip.

The vessels *occupy* the outer side of the funnel and *leave* a pyramidal space, the **femoral canal**, on the inner side of the vein and separated from it by connective tissue, belonging to the fibrocellular or proper sheath of the vessels. This canal *measures* one half to three fourths inch in length, and tapers to its *lower closed end* which is *opposite* the upper end of the saphenous opening. It is only a *potential canal*, like the inguinal, not a real one unless made so by a hernia or the knife. It represents a *weak spot* which forms the passage way of a femoral hernia.

The femoral canal is *bounded* externally by the femoral vein with a septum of connective tissue between, and on the other sides by the femoral sheath. It *contains* fatty and cellular tissue, lymphatics penetrating its anterior wall and passing from the superficial to the deep inguinal nodes, and one or more lymph nodes. Its upper or *abdominal aperture* is the oval *femoral ring*, mentioned above. The size of the ring varies, but is usually sufficient to admit the tip of the forefinger. It averages three fifths of an inch in diameter in the male and is half again as large in the female, hence the *greater frequency of femoral hernia in women* in the ratio of three to one. Its *greater width in women* is not due to any greater width of the space beneath Poupart's ligament, for it is not wider, but to the smaller size of the muscles, occupying the muscular compartment, and of Gimbernat's ligament.

When viewed from above the *femoral ring* is seen to be covered by peritoneum, which may present a slight depression, the *fossa femoralis*. According to Tillaux, such a depression is not normal but pathological, the peritoneum being drawn down by an attached fat lobule belonging to the subperitoneal tissue.

On removing the peritoneum the ring is seen to be closed by the

**septum crurale** (Cloquet), a condensed layer of connective tissue, continuous with the subperitoneal tissue and *perforated by lymphatics* passing from the inguinal to the iliac nodes. A small *lymph node* is sometimes found lying on it. Inflammation of this gland or of one in the canal has been mistaken for strangulated hernia, on account of a similarity of symptoms.

FIG. 69.

Section of the crural canal and of the muscular and vascular compartments beneath Poupart's ligament. (TILLAUX.)

**The boundaries of the ring** are of great practical importance from their relation to the neck of a femoral hernia. To the *outer side* lies the vein in its sheath, elsewhere the boundaries are of firm fibrous structures. *In front* lies the superficial femoral arch (Poupart's ligament) and the deep femoral arch (see p. 270). *Behind* is the thin upper end of the pectineus muscle, resting on the horizontal pubic ramus and covered by the thickened upper end of the pectineal fascia. *Internally* there is a series of firm fibrous structures, attached to the iliopectineal line, as follows from below upward: the iliac portion of the fascia lata, Gimbernat's ligament, the triangular ligament, the conjoined tendon, and the deep femoral arch. These structures present a *sharp free margin* towards the ring.

**Relation of Parts About the Ring.**—The *spermatic cord* in the male and the *round ligament* in the female lie in loose tissue one fourth to one fifth of an inch above the *anterior margin* of the ring. The *epigastric vessels* lie above and to its outer side, distant about half an inch. The small pubic branch of this artery runs across in front

of the ring, to ramify on the upper aspect of Gimbernat's ligament. These structures are in danger of being divided by a free incision upwards but, according to Tillaux, not by an incision or incisions of one fifth of an inch, which may subsequently be enlarged by the finger.

The *internal* and *posterior aspect* of the ring are usually *free* from important relations. Therefore to relieve the constriction in a strangulated hernia we may *incise backward*, but little room is to be gained here as only a thin layer of soft parts covers the bone. Hence we *incise inwards*, bearing in mind the following *variations*.

Once in every  $3\frac{1}{2}$  cases the *obturator artery* is given off as a *branch of the epigastric artery*. The *course of this branch* is commonly to the outer side of the ring, where it lies close to the vein, and not exposed to injury by incision, for we never incise outwards on account of the vein. *Occasionally* (in 1 to  $3\frac{1}{2}$  per cent.) the common trunk is longer, crossing in front of the ring, and the *obturator branch*, with its vein, passes back close to the *inner border of the ring* where artery and vein are exposed to injury by a free incision inwards. Cases are recorded where such an injury has resulted fatally, and the reason why it is not more frequent seems to be that the vessels lie in loose tissue, 1 to  $2\frac{1}{2}$  lines from the edge of the ring, and may be readily pushed back before the knife, and also that multiple short incisions are often employed.

If the finger can be pushed through the ring the *pulsation* of such an aberrant artery, lying internally, may be *felt*. It should be sought for so as to avoid the chance of an accident.

The *size and the tension* of the femoral ring and canal and of the saphenous opening, and hence the constriction of a hernia passing through them, *varies with the position* of the limb. They are *enlarged and relaxed* in flexion, adduction, and inward rotation of the thigh and hence taxis should be tried in this position. In the reverse position these parts are rendered tense by the traction of the fascia lata upon Poupart's ligament.

**Femoral hernia** is *always acquired*, never congenital. It occurs almost exclusively in *adult life*. Though more common in women than in men in the ratio of 3 to 1, it is *less common in women than the inguinal variety*, contrary to the general impression. The weakening effect of pregnancy on the abdominal walls increases the liability of women to femoral hernia, so that it is more common after the first pregnancy.

**Course and Coverings.**—A pouch is gradually formed of the peritoneum covering the weak spot, the femoral ring. This forms the hernial sac and a covering is received from the septum crurale in passing through the ring beneath Poupart's ligament. The hernia *descends vertically* in the femoral canal to its *lower end*, opposite the saphenous opening. Here it *turns forward* and then *upward and outward* toward the anterior superior iliac spine, even as far as Poupart's ligament, receiving a covering from the femoral sheath and the cribriform fascia. It thus comes to lie beneath the skin and subcutaneous tissue.

Various reasons have been adduced to explain the curved course of

PLATE XXXIII.

FIG. 67.

Rear view of anterior abdominal wall, showing right inguinal and left femoral hernia. The obturator artery is given off by the epigastric, the dotted line on the left showing another, rarer and more important form of this variety. (Joessel.)

the hernia. (1) The canal curves slightly with the concavity forward. (2) The downward course is limited by the lower limit of the canal and the firmness of the lower margin of the saphenous opening which is closely united with the femoral sheath and the cribriform fascia. (3) The constant flexion of the thigh. (4) The loops formed by the vessels passing down to the saphenous opening loop up and prevent the descent of a hernia. (5) The traction of the mesentery.

The *course* of a hernia should be *borne in mind in applying taxis* in the reverse direction for its reduction.

From the above we may summarize the *coverings* from without as follows: (1) skin; (2) subcutaneous tissue; (3) cribriform fascia; (4) anterior wall of the femoral canal (femoral sheath); (5) septum crurale; (6) peritoneal sac.

The *sac* of such a hernia comes to lie very close beneath the skin. One or more of Nos. 3, 4 and 5 may be *broken through* instead of pushed before the hernia so as to be wanting as a covering, and the *torn opening* of such layer or layers may be the *seat of constriction*. Nos. 4 and 5 (or 3, 4, and 5) often matted together and combined to form a single covering, were called *fascia propria* by Sir A. Cooper. It is often impossible to distinguish the separate layers as they may be thinned out and adherent to one another. In case of a hernia confined to the upper part of the canal, the iliac portion of the fascia lata forms a covering between the femoral sheath and the superficial fascia in the place of No. 3.

A hernia confined to the canal is small, owing to the unyielding character of its fibrous walls, and is generally readily reducible as the neck is as large as the rest of the hernia. After protruding at the saphenous opening into the loose subcutaneous tissue of the groin a femoral hernia may attain considerable size.

The *contents* are not characteristic; *omentum* is very often present and apt to be adherent, intestine is less often present than in inguinal hernia but is more likely to be strangulated. In the latter case the *seat of the constriction* is often in the neck of the sac, but more often outside of it than with the inguinal variety. It occurs at the curved margin formed by Gimbernat's ligament, etc., or, according to some, at the margin of the saphenous opening.

**Herniotomy.**—The *incision* may be parallel to Poupart's ligament and over the tumor, or vertical and on its inner side. Poupart's ligament should be exposed as a landmark. In large herniae the overlying layers may be few in number or much thinned out, so the incision should be made with care. The amount of subperitoneal fat is sometimes very great so as to simulate omentum while the thinned fascia propria may be mistaken for the sac. In such a case, after enlarging the ring, the real sac embedded in fat may be reduced with its contents and, if the constriction be in the neck of the sac, the strangulation would not be relieved. In operating I have not infrequently found this fat so abundant that, in a tumor of some size, it was not easy to find the small sac. We incise the constriction inward, inward

and backward, or inward and forward (Cooper). The small external pudic vessels lie behind the hernia and therefore are not cut by the incision.

In *Bassini's radical operation*, after removing the sac high up, the canal is closed by suturing the inner end of Poupart's ligament and the falciform edge of the fascia lata to the pectineal fascia (*i. e.*, the pubic portion of the fascia lata).

In the diagnosis between femoral and inguinal hernia, *Poupart's ligament* and the *pubic spine* are the two important *landmarks*. The neck of a femoral hernia is below the former and external to the latter; that of an inguinal hernia has the opposite relations, though it often crosses the spine, lying in front of it.

The diagnosis is easy in scrotal herniæ, in thin subjects, and when the herniæ are reducible so that the relations of the neck of the sac to the landmarks can be examined. It is easier in men than in women because of the greater ease of examining the inguinal canal in the former. In women, owing to its small size, the inguinal canal can only be satisfactorily examined when there is an inguinal hernia. In irreducible herniæ we must depend upon the position of the hernia relative to Poupart's ligament and the pubic spine, a femoral hernia being altogether below the former and external to the latter. In fat subjects we may not be able to feel Poupart's ligament even in its inner half, but the furrow of the groin nearly corresponds to it, or we may draw a line between its bony attachments, finding the pubic spine in males by invaginating the scrotum.

So-called *hernia adiposa* is not a real hernia but, from its position and form, it may give difficulty in diagnosis here as with other forms of hernia. It is a *lipoma of the subperitoneal tissue* which in its growth takes the same course as a hernia. It is *irreducible* and tends to draw the peritoneum after it, thus forming a pouch which may be the starting point of a true hernia.

**Irregular and rare forms** of femoral hernia may occur: (1) To the outer side of the artery; (2) hourglass-shaped hernia due to the escape of a part of the hernia through a rent in one of the covering layers, generally the cribriform fascia; (3) within the proper sheath of the vessels, etc.

## POSTERIOR ABDOMINAL WALL.

### Iliac Region.

This region, the lowest part of the posterior abdominal wall, corresponds to the iliac fossa and is *bounded* below by Poupart's ligament, internally by the pelvic brim (iliopectineal line), above and externally by the iliac crest. The right and left iliac fossæ are separated from each other by the pelvic cavity. It is comparatively small in children and attains its size about the time of puberty. It can be *examined* only through the abdominal wall which should be relaxed by flexion of the thigh.

In studying this region layer by layer from before backwards, we notice :

1. **Parietal Peritoneum.**—This becomes continuous with that lining the antero-lateral abdominal wall along the iliac crest and Poupart's ligament, where it is loosely attached by means of the next layer so as to be easily raised up.

2. **The subperitoneal tissue** is here very abundant and loose, and contains more or less fat. It is continuous with the like layer in the neighboring regions of the abdominal parietes, the antero-lateral region below and externally, the lumbar above and the pelvis internally (the latter including the tissue between the folds of the broad ligaments in the female).

Its looseness favors the spread of abscess. Such an abscess may originate in a viscus which occupies this region, the cæcum or appendix on the right, the sigmoid flexure on the left. The infection may reach this layer by passing along the lymphatics or the tissue lying between the layers of peritoneum which attach the viscera. On the other hand an abscess in this tissue may perforate and discharge into one of these viscera. Again such an abscess may sink down from the lumbar region or rise up from the pelvis, as in cases of retroperitoneal pelvic abscess or pelvic cellulitis in the female.

Abscess in this tissue is more common on the right side owing to the presence of the appendix. As a rule it sinks to the level of *Poupart's ligament* and here it collects and displaces upward the peritoneum from the iliac fascia behind and the transversalis fascia in front and "points" above *Poupart's ligament*. In this position it may be opened by incising the transversalis fascia and the overlying layers without opening the peritoneum which is displaced upward. This was the course of many abscesses originating in the appendix, the so-called *perityphilitic abscesses*, before the adoption of the modern operation for appendicitis.

Many cases of abscess resulting from pelvic cellulitis open or are opened here. Occasionally pus collecting here escapes into the upper and inner aspect of the thigh through the femoral ring or along the iliac vessels, which lie in this layer, or it may sink into the pelvis.

**Structures in the Subperitoneal Layer.**—The external iliac artery and vein, spermatic or ovarian vessels, genitocrural nerves, ureter and vas deferens.

**External Iliac Vessels.**—The course of the artery is represented by a line, curved slightly outward, from a point half an inch to the left and below the umbilicus and directed downward and outward to Poupart's ligament, a little internal to its center, or half way between the anterior superior iliac spine and the symphysis pubis. The upper two inches of this line would represent the common iliac artery, the lower two thirds or the part below the level of the lumbosacral junction the external iliac.

The vein lies to its inner side, inclining behind it above on the right side so as to reach the outside of the right common iliac artery.

**Position.**—These vessels lie upon the inner border of the psoas muscle along the brim of the pelvis in the fibrocellular sheath, connected with the iliac fascia which separates it from the muscle.

**Relations.**—The external iliac vessels are crossed *in front by* the sigmoid flexure on the left and the end of the ileum on the right side. The ureter sometimes crosses over their upper end instead of over the bifurcation of the common iliac vessels. The spermatic vessels and the genital branch of the genitocrural nerve lie upon the lower part of the artery for a short distance, and the deep circumflex iliac vein crosses it just above its lower limit. The vas deferens in the male, and the round ligament and ovarian vessels in the female, cross it to reach the pelvis. The crural branch of the genitocrural nerve descends in front of the artery.

These relations should be borne in mind in ligature of the *external iliac artery*. In this operation, whose principal indication is *femoral aneurism*, the most important *relations* are those of the vein, for the ligature is passed from the venous side, and the relations to the loose subperitoneal tissue, for the latter allows the exposure of the vessel by permitting the raising up of the peritoneum from the iliac fossa through an incision along the lower or outer border of the region.

The incision may be made : (1) slightly above and *parallel with* the outer half of *Poupart's ligament*; or (2) *parallel with* and over the course of the *artery*, a little external to the course of the deep epigastric so as to avoid the latter, and commencing a little above Poupart's ligament.

In (1) we *incise* through the external oblique aponeurosis and then, retracting upward the outer end of the free edge of the conjoined tendon at the inner angle of the wound, we may incise the latter along its attachment to the outer half of Poupart's ligament, to gain room. Then incising in the same line the transversalis fascia, we expose the loose subperitoneal tissue, in which the artery lies in front of the iliac fascia. In this tissue at the inner angle of the incision we may expose the deep epigastric artery, which should be retracted upward and inward. The peritoneum is then bluntly detached from the iliac fossa, from its reflection behind Poupart's ligament upward and inward to the inner border of the psoas, which forms a convenient landmark for the artery.

There is *danger* of wounding the deep circumflex iliac vessels by incising too close to Poupart's ligament and of wounding the deep epigastric vessels by incising too far internally. Mesially the incision is not commonly carried beyond the level of the internal abdominal ring, as that is slightly internal to the middle of Poupart's ligament, but even if it should be there is half an inch between the ligament and the ring, so that the latter need not be injured unless the incision is too high.

After separating the artery from the vein, through the loose tissue which forms a kind of sheath for it, the *artery* is *tied* about  $1\frac{1}{4}$  inches above Poupart's ligament to avoid the proximity of collateral branches and important relations. The operator should avoid including the crural

branch of the genitocrural nerve in the *ligature* which is passed from within outwards.

In (2), the principle is the same, namely bluntly detaching the peritoneum from the iliac fossa from its reflection behind Poupart's ligament in an upward and inward direction. The artery is exposed at greater depth and there is more danger of hernia, but the deep epigastric and circumflex iliac vessels and the internal ring are in no danger. The artery may also be tied higher up and the skin incision is further from the groin in case an aneurism bulges there.

At the present day the *transperitoneal method* is more often employed than formerly, and this allows of ligature high up or of ligature of the common iliac, if necessary. The chief objections are those common to abdominal incisions in the semilunar line (see p. 253), unless the intermuscular method is used.

The common iliac artery may be reached and tied extraperitoneally by an extension of the *incision* (1) for the external iliac upward toward the lower ribs, or upward and inward toward the umbilicus. This operation is very rarely called for. I have found McBurney's suggestion, the compression of the common iliac by the finger of an assistant introduced through an oblique intermuscular abdominal incision, most efficient and useful in amputation at the hip joint.

The collateral circulation after ligation of the external iliac artery is derived from the *anastomosis* of the deep epigastric with the internal mammary, obturator, lumbar and lower intercostals; of the deep circumflex iliac with the iliolumbar; of the internal circumflex with the obturator; of the external circumflex with the gluteal; of the external pudic with the internal pudic, and other minor anastomoses.

The external iliac lymphatic nodes extend in a chain of about five along the anterior and inner aspect of the external iliac vessels. As they receive the lymphatics from the inguinal nodes and the vessels accompanying the deep epigastric and deep circumflex iliac arteries they may be enlarged from infection from these sources. We may palpate them, when enlarged, through the abdomen, except in very fat subjects, and so determine the extent of the lymphatic infection in septic or cancerous cases. These nodes when enlarged may cause persistent oedema of the lower extremity by pressure on the external iliac vein.

The iliac fascia covers the iliopsoas muscle and is attached to bone and fascia around the limits of this muscle, thus forming for it a single osseo-fibrous compartment. At the most dependent part the muscle and fascia pass into the thigh. The upper part sheathes the upper part of the psoas and is thin and adherent to it. It ends above at the diaphragm in a thickening, the ligamentum arcuatum internum, and is attached, along the outer border of the psoas, to the anterior layer of the lumbar fascia. The lower part, covering the iliacus and the lower part of the psoas, is thicker and separated from the muscle by a thin layer of fatty connective tissue which favors the formation or spread of pus. In this loose tissue lie the anterior crural and external cutaneous nerves, and some muscular arterial

branches. The large vessels are therefore separated by the iliac fascia from the principal nerves of this region, save the genitocrural. The lower part of the fascia is *attached* to the iliac crest externally and above, to the iliopectineal line internally, while inferiorly it is adherent to the outer 4 cm. of Poupart's ligament and continues under the latter into the thigh as the sheath of the muscle as far as its insertion. *Internal to the muscle* it passes into the thigh behind the vessels, whose sheath it helps to form, and is *continuous with* the fascia covering the pecten, *i. e.*, the pectineal fascia or the pubic portion of the fascia lata. Between the iliopsoas and the pecten it sends back a *fibrous partition* to the pectineal eminence and the capsule of the hip.

Although in surgery we find that abscesses do not always respect fibrous fascial planes, but sometimes break through them, this is less true of those beneath the iliac fascia, especially in the case of "cold" or tubercular abscesses.

*Abscesses beneath the iliac fascia* are often known as "*psoas abscesses*" and have a quite definite *course*. They sink by gravity along the course of the muscle, pass under the outer half of Poupart's ligament and *point* at the upper and anterior part of the thigh, external to the large vessels, where they may be safely *opened*. Occasionally they do not take this course, but may point elsewhere after breaking through the fascia. They may extend into the lumbar region, over the iliac crest into the gluteal region, over the pelvic brim into the pelvis, or along the inguinal canal into the scrotum and find an exit in the parts named. They may also open above instead of below the fold of the groin. In other cases I have seen a psoas abscess pass lower into the thigh, probably following branches of the anterior crural nerve where they pierce the sheath of the iliopsoas.

We call these abscesses "*psoas abscesses*" because most of them are *due to spinal caries* and make their way first into the sheath of the psoas. If the *caries* is *in the lumbar spine* direct extension into the psoas muscle readily occurs. The lumbar curve is likely to be flattened out in such cases. Instead of entering the psoas sheath such abscesses may pass behind it and enter and point in the lumbar region, or they may extend between the muscular and fascial planes of the anterior belly wall. If the *caries* is *in the thoracic vertebrae* the pus descends by gravity in the posterior mediastinum along the front of the spinal column to the upper end of the psoas. This it penetrates, like a wedge, between its upper origins, *i. e.*, from the body and the transverse process of the first lumbar vertebra, at the same time passing under the ligamentum arcuatum internum. The pus more or less entirely destroys the muscle, leaving the lumbar nerves free in a pus sac.

In inflammation of the iliopsoas, or in psoas abscess before the pus is evacuated, the *thigh is kept flexed*, for in this position the muscle is most relaxed, the abscess is least tense, and the lumbar nerves less compressed and irritated. This *relaxation* is *due to* the fact that flexion of the thigh is the principal action of the iliopsoas; the outward rotation, sometimes associated with it, is due to other causes, for the ilio-

psoas is not an outward rotator. According to Hyrtl the iliopsoas cannot alone, or even with the pectenous, flex the thigh, so that in high amputation of the thigh the patient cannot flex the stump until the other flexors have become adherent to the scar or to the bone.

Abscess similar in course to the foregoing may arise in the iliac fossa which might properly be called "*iliac abscess*," but this term is more often applied to those in the iliac subperitoneal tissue.

In psoas abscesses the fold of the groin is partly effaced in its outer part, fluctuation may be obtained below Poupart's ligament and a fullness is felt in the iliac fossa or, in thin patients, along the course of the psoas.

From the above we see that two well-marked forms of abscess occur in the iliac region, (1) in the subperitoneal tissue and (2) beneath the iliac fascia, separated as to their position by the iliac fascia.

The ilium, forming the iliac fossa, separates this region from the gluteal region behind, hence pus in this region sometimes gains access to the gluteal region by a perforation of the thin translucent bone. The posterior drainage of some cases of abscess in the iliac fossa, through a trephine opening in the bone, has been advised and practised, according to the principle of drainage at the most dependent point, *i. e.*, in the supine position.

*Tumors*, especially enchondroma and osteo-enchondroma, occasionally take origin from the iliac bone or its periosteum. *Fracture* from direct violence may involve almost any part of the ilium, the fossa, the superior spine or the crest. The latter may be separated entire as an epiphysis previous to about the twenty-fourth year, when it joins the bone. In fractures through the fossa the fragments are usually held in position by the muscles attached on either side, which act as splints. Owing to the many muscular attachments, absolute rest is required in the treatment of fractures of the ilium.

### Lumbar Region.

The two lumbar regions, right and left, adjoin one another in the median line and are bounded above by the twelfth ribs; below by the posterior half of the iliac crests; and laterally by the external border of the external abdominal oblique muscles.

**Superficial View from behind.** In the median line we see a vertical groove, the *spinal furrow*, which is due to the prominence of the erector spinae mass on either side and to the attachment of the skin, by means of the subcutaneous tissue, to the tips of the lumbar spinous processes, which we feel in the bottom of the groove. The spinal furrow spreads out below into the angular interval between the gluteal muscles. The lateral margins of the erector spinae muscle can be felt and usually seen, except in fat subjects. Lateral to the erector spinae mass the surface is flattened. The backward projection of one or more of the spines indicates an injury or a disease, probably caries of the bodies of the corresponding vertebræ.

Normally the line of the lumbar spines and the contour of the lumbar region is vertically concave, and slightly more so in women than in men. In *hip joint disease*, when the joint is ankylosed in the flexed position, this concavity is much increased by extending the thigh, giving rise to the deformity known as *lordosis*, and it is flattened out on flexing the thigh beyond the angle at which it is ankylosed. These are important diagnostic points, and are due to the very free flexion and extension in the lumbar vertebræ, which tilt the pelvis and take the place of the similar movements in the hip.

A horizontal line connecting the highest points of the iliac crests corresponds to the spine of the fourth lumbar vertebra. In the interspace above (or below) this spine *lumbar puncture* is practised, one fifth to two fifths of an inch from the median line. This is below the spinal cord, which reaches to the top of the second lumbar vertebra.

**The subcutaneous tissue** is a thick dense layer containing but little fat and connected closely with the skin but only loosely with the fascia beneath, thus allowing large extravasations of blood or of a sero-sanguineous fluid from glancing blows.

**Superficial Muscles.**—The *latissimus dorsi*, like the external abdominal oblique, is attached to the outer lip of the iliac crest. At the mid point of the crest an *interval* between these two muscles usually exists, which is *triangular* in shape owing to their converging above. This triangle, with its base below, is known as the *triangle of Petit* and is a weak spot representing a lack of one of the muscular layers. Hence it is that a rare form of hernia, *lumbar hernia*, occurs here and it is a favorite spot for the pointing of lumbar abscesses. Its *floor* is formed by the internal oblique muscle, which overlaps the external oblique posteriorly and thus comes in contact with the subcutaneous tissue in this small triangular area.

Both the internal oblique and the *latissimus dorsi* are attached to the dense posterior layer of the *lumbar fascia*. (Fig. 70.)

**The lumbar fascia**, the *posterior, middle, and anterior layers* of this fascia are attached mesially to the tips of the lumbar spines, the tips of the lumbar transverse processes and the front of the bases of the latter respectively. Laterally they join together and thus sheath and form an osseofibrous *compartment* for the two vertical muscles of this region, the *erector spinae* and the *quadratus lumborum*.

The posterior joins the middle layer of the fascia at the outer border of the *erector spinae*. The middle layer, thus reinforced, joins the anterior layer of the fascia at the outer border of the *quadratus lumborum*. The combination of these three layers, about three inches from the tips of the lumbar transverse processes, forms a fascia which gives origin to the *transversalis* muscle and hence is called the **posterior aponeurosis of the transversalis muscle**, a name sometimes applied to the entire fascia. The posterior layer forms a part of the thick *vertebral aponeurosis* covering the muscles of the back.

The *posterior and middle layers*, where they form the sheath of the *erector spinae*, are very thick and strong, hence abscesses seldom if ever

## PLATE XXXIV.

FIG. 70.

Transverse section at level of the second lumbar vertebra, to show the position of the kidney, the lumbar fascia, and the posterior attachment of the abdominal muscles (the external oblique is drawn too near the median line).

penetrate the erector spinæ muscle unless they originate in the bones of the neural arch with which the muscle is in contact. On the other hand the *anterior layer*, covering the front of the quadratus lumborum, is very thin and is in contact with the subperitoneal connective tissue and fat in relation with the kidney and colon.

The lumbar fascia is very *variously described*. Some (Joessel) describe two layers, a superficial or posterior, and a deep layer, the third or anterior layer being called the transversalis fascia. Others (Gray) describing three layers as we have done above, speak of the anterior layer as identical with the transversalis fascia. Others again (Morris) describe the transversalis fascia as ending laterally in the loose fat behind the kidney while the three layers of the lumbar fascia are described as above. Tillaux describes two layers and a division of the posterior layer so as to invest the erector spinæ mass. The term lumbar fascia or aponeurosis he applies only to the layer behind the erector spinæ.

On the whole the weight of authority makes the transversalis fascia continuous with the anterior layer of the lumbar fascia; the other differences of description are of no practical importance. The important point is that we have three fascial layers, forming two muscular sheaths, continuous with the posterior aponeurotic attachment of the transversalis muscle, giving attachment to other muscles and directing the course of abscess, etc.

**Abscess** starting in the lumbar subperitoneal tissue may readily perforate the anterior fascial layer, enter and pass through the thin quadratus muscle, and perforate its posterior sheath external to the outer border of the erector spinæ. Or it may perforate the posterior aponeurosis of the transversalis external to the quadratus muscle. In certain cases this may be facilitated by the abscess following the last thoracic or the iliohypogastric nerves where they pierce this aponeurosis, below the last rib and above the iliac crest respectively. In either case the abscess comes to lie under the internal oblique and its posterior aponeurotic attachment. The common course is then to perforate the latter and sink to the triangle of Petit or to the outer border of the erector spinæ, where it appears as a **lumbar abscess**.

**Muscles.**—The thick **erector spinæ** has a dense fascial sheath which we avoid opening in lumbar incisions, for little or no room is thereby gained and we thus avoid the danger of suppuration within the sheath. The erector spinæ mass *occupies* the entire vertebral groove on each side and projects beyond it laterally. It forms a marked projection on each side of the median line, which thus presents a furrow. Its *outer border*, limited by the union of the posterior and middle layers of the lumbar fascia, is readily felt and forms an excellent landmark in making transverse lumbar incisions.

The thin flat **quadratus lumborum** is one third broader than the erector spinæ and thus extends beyond it laterally, where it is itself overlapped by the internal oblique. The outer third of the thin quadratus muscle, unsupported by the erector spinæ, offers less resistance to

protrusions from within than the inner two thirds. The outer border of the quadratus lumborum forms the most valuable *landmark in lumbar operations*. This border is not vertical but inclines inward as it passes upward. Just above the iliac crest it corresponds to a line drawn vertically from the middle of the crest, hence it corresponds to the position of Petit's triangle. Midway between the crest and the last rib it may be about an inch internal to the above line.

**Incisions.**—Vertical lumbar incisions are made from a point one half to one inch mesial to the middle of the iliac crest, so as to meet the outer border of the quadratus about the middle of the lumbar region. This line of incision also corresponds to the course of the colon. This vertical incision is objectionable because it divides the lumbar and last thoracic vessels and nerves, which cross its course, and it affords comparatively little room. Hence an oblique incision, commencing in the costo-vertebral angle not far internal to the outer border of the erector spinae, is preferable as it parallels the vessels, the nerves and the natural creases and cleavage lines of the skin of this region. If, as is often done, we incise just below the *twelfth rib* the latter should be determined by counting from above, for Dr. Holl has shown that the rib is frequently rudimentary and so short as not to reach beyond the erector spinae mass, so as to be mistaken for a lumbar transverse process. If the incision should then be made just below the eleventh rib the *pleura* would be *in danger* of being opened, an accident that has been recorded by Professor Dumreicher of Vienna and others. In these cases the lower edge of the pleura extends from the lower border of the last thoracic vertebra nearly horizontally to the lower border of the eleventh rib. Exceptionally also the pleura may project considerably below a normal twelfth rib, so as to require caution in any case at the inner and upper angle of the incision. The fact that we may have a correspondingly high level of the pleura with a rudimentary twelfth rib makes the above caution no less imperative in all cases.

The oblique incisions extend laterally a variable distance beyond the lumbar region, and divide in the superficial muscular layer, the latissimus dorsi and the external oblique; in the next deeper layer the internal oblique and its posterior aponeurosis; and beneath this the transversalis and its posterior aponeurosis, including that part of it forming the dorsal layer of the sheath of the quadratus muscle. Retracting the outer border of the latter muscle inwards, or incising it if necessary to gain more room, we incise its anterior fascial covering, and the transversalis fascia continuous with it, and reach the *subperitoneal connective tissue* in relation to the kidney and colon. It is in this tissue, which here contains much *fat*, that *perinephritic abscess* develops. We have shown above its most common course (Lumbar abscess, p. 281) but it may also sink in the subperitoneal tissue into the iliac fossa or pelvis, and not infrequently it burrows through the diaphragm and parietal pleura and so enters the pleural cavity (p. 212).

**The vessels** are the subcostal (twelfth or last thoracic), and the four lumbar arteries and their accompanying veins. Of these the sub-

costal and first lumbar, and sometimes the last lumbar, pass outward in front of the quadratus lumborum, and behind the anterior layer of the fascia, the others lie behind the quadratus. Beyond the lateral border of this muscle they pass forward between the muscular layers of the anterior abdominal wall and anastomose with the vessels found there, as well as with those above and below. The *veins* on either side are connected by a vertical trunk, the *ascending lumbar vein* which, continued into the azygos vein of each side, furnishes an anastomotic course in case of obstruction of the inferior cava.

**Lymphatics.**—The superficial vessels empty into the inguinal nodes, the deep lymphatics accompany the blood vessels and empty into the lumbar nodes along the abdominal aorta.

**Nerves.**—The twelfth thoracic and the iliohypogastric and ilioinguinal branches of the first lumbar nerves *lie* in front of the quadratus lumborum and behind the anterior layer of its sheath; the first named a little below and parallel with the twelfth rib, the others nearly parallel with it and successively lower. The three nerves just named *pass* behind the kidney obliquely from within and above, outward and downward. *Pressure* upon them by a perinephritic abscess or a large tumor of the kidney may give rise to *pain* in the areas of their distribution. Thus in a case of perinephritic abscess I have seen the principal pain in the lateral gluteal region and over the outside of the hip which are supplied respectively by the large lateral cutaneous branches of the last thoracic and the iliohypogastric nerves. The same renal lesions may cause *flexion of the thigh* from pressure on the branches of the second and third lumbar nerves supplying the iliopsoas and pectenous muscles.

The *obliquely transverse direction* of the vessels and nerves of this region renders them liable to division by a vertical lumbar incision, but not by an obliquely transverse one, a point of superiority of the latter incision. The small size of the vessels renders their division comparatively unimportant.

**Lumbago** is a painful affection of the lumbar region depending upon several different causes. It may be *due to* a strain of the muscular or fibrous tissues of the region, from a violent exertion; to muscular rheumatism; or to a neuralgia or a neuritis of the nerves, giving rise to painful areas in the distribution of the nerves. *Sympathetic lumbago* may be due to a variety of causes; disease of the vertebrae, spinal cord, kidney and urinary apparatus, or infectious fevers (grippe, smallpox, etc.).

**Wounds** of the region are *rare*, and are likely to be serious only when lateral to the erector spinae mass, where the abdominal wall is thinner. Contusions may cause an injury to the viscera (kidney most often, possibly also the colon) without any appreciable sign of injury superficially.

In the reclining position the peritoneal aspect of the lumbar region is on a lower level than that of the iliac fossa, hence pus or other fluid, if free in the latter region, tends to gravitate to the former. This is

to be carefully borne in mind in operating for appendicitis and this course, which may be taken by pus external to the cæcum and colon, should be closed by gauze packing.

### THE ABDOMINAL CAVITY.

The *form* of the cavity is that of an oval with its larger end above. Owing to the obliquity of the diaphragm, the **main axis** of the cavity is oblique from above downward, forward and to the right, and is directed to the right pubic spine. This is given as one reason for the greater frequency of hernia on the right side. The obliquity of the *axis of the pelvis* is from above downward and backward, so that in parturition and forced defecation or urination the body is flexed to bring these two axes in the same vertical plane, so that the abdominal pressure may act to the greatest advantage in the pelvis.

The abdominal cavity is *not identical with the peritoneal cavity*, for several of the abdominal viscera are *extraperitoneal*, being only partly covered by peritoneum (kidney, duodenum, etc.). Such viscera may be wounded or operated upon without involving the peritoneum which is necessarily involved under similar circumstances in the case of the *intraperitoneal viscera* (stomach, small intestine, spleen, liver, etc.). Similarly *peritonitis* is very apt to be caused by inflammation or perforative ulceration of the intraperitoneal viscera, but not necessarily by that of the extraperitoneal viscera. Thus a large perinephritic abscess, due to a diseased kidney, very rarely involves the peritoneum, while inflammation of the appendix or perforation of the small intestine sets up a local or general peritonitis.

### The Peritoneum.

The **parietal peritoneum** *lines* the deep surface of the abdominal wall and the extraperitoneal viscera. It is thin above, thicker below and behind, where its more abundant and fatty subperitoneal tissue connects it loosely with the abdominal wall, allowing it to be stripped up in operations or by inflammations. At the umbilicus it is closely adherent to the belly wall and somewhat less adherent along the back of the linea alba.

A **penetrating wound** of the abdomen is one which penetrates the peritoneum as well as the other layers of the parietes. Such wounds are much *more serious* than those which reach to but not through this layer for, while it is easy to set up inflammation (peritonitis) from its inner surface, the outer surface may be bathed with the pus of an abscess or extensively stripped up in operations without ill effects. The fact of penetration in an abdominal wound is often difficult to determine clinically and, in the absence of definite symptoms, we are justified in enlarging bullet and stab wounds, rather than in exploring with the probe.

The peritoneum is *capable of great stretching* if it is effected gradually, as seen in the pregnant uterus, the distended bowel, a hernial

sac, or an abdomen distended from various causes. According to Huschke it is capable of bearing a weight of fifty pounds, and its elasticity is well shown by returning to its previous condition after removal of the weight as well as, during life, after the removal of ascites, large abdominal tumors and the foetus at term. It is possible for the parietal peritoneum to be ruptured by an injury which does no damage to any of the viscera. Inflammation of the peritoneum and its results interfere with its distensibility and elasticity, and may thus disturb the functions of those organs which are covered by peritoneum and vary in volume (uterus, intestine, bladder, etc.).

Like other serous membranes the peritoneum shows a strong tendency to adhesion between two opposed surfaces which are irritated or inflamed. By the stretching of these adhesions there may be formed a variety of bands beneath which loops of intestine may be caught and strangulated. The tendency to adhesion is made use of in intestinal suture in which the peritoneal surfaces are turned in so as to oppose one another. Firm adhesion occurs much sooner than when other soft parts are united by suture. Peritoneal adhesions, whether purposely formed or the result of inflammation, often show a tendency to become smaller, longer, and eventually to disappear, when the cause of irritation is removed.

The peritoneal cavity is merely a capillary interval between the contiguous surfaces of the viscera which are covered by peritoneum, and between them and the parietal peritoneum. It is a closed serous sac except in the female, where the openings of the Fallopian tubes connect it indirectly with the body surface. This sac contains just enough peritoneal fluid to lubricate the surfaces and diminish friction. As a result of venous congestion a large amount of serous fluid may be effused into the peritoneal cavity. This is known as ascites (from *αστος*, a skin bottle) and depends upon obstructed venous flow in the heart or lungs, if there is dropsy elsewhere, otherwise the obstruction is probably in the liver. If the fluid is small in amount it collects in the flanks on lying down, or the hypogastric or inguinal regions on sitting up; if in greater amount it distends the belly, and the intestines float on top in whatever position the body is in. The fluid is dull or flat on percussion and sharply marked off from the tympanitic resonance of the intestines. Breathing may be easier in the sitting posture, for the compressible intestines then lie beneath the crowded-up diaphragm.

Tapping of ascites may be practiced in the semilunar line or the linea alba. When the fluid is partly withdrawn the end of the trocar is sometimes closed by the omentum or intestine, which can be dislodged by introducing a probe. As the withdrawal of the fluid, by reducing the intra-abdominal pressure, causes a distension of the deep abdominal veins and thereby robs the heart of its wonted supply, faintness is liable to occur, but may be prevented by the pressure of an abdominal binder.

The surface of the peritoneum is about equal to that of the skin, hence its enormous absorbing function, taking up in one hour three to eight per

cent. of the body weight. An equal *transudation* or exudation may occur from very toxic or irritant substances. Fluids may pass through the endothelial layer in many places; solids are carried largely by leucocytes and are said to pass only through the intercellular spaces of the peritoneum covering the diaphragm and thence into the mediastinal lymph nodes. The presence of stomata is denied by Muscatello.

There is normally a force in the peritoneal cavity which carries fluids and foreign particles toward the diaphragm, regardless of the position of the body though either retarded or favored by it. The peritoneum in a healthy state is capable of *disposing of* a large number of *bacteria*, even of pyogenic varieties, without ill effects; but if there is a lesion of the membrane, or anything to arrest the normal absorption, so that the bacteria may stagnate and multiply, peritonitis results.

If, about the focus of a commencing peritonitis, the surrounding parts become glued together by a plastic exudate on the peritoneal surface, the *peritonitis* may be limited or *localized*, as in most cases of appendicitis. If the adhesions are imperfect, or do not develop, or the focus is more diffused, the peritonitis is *progressive* until it becomes *general*. The latter is the more acute form and in it the muscular coat of the bowel and its nerve plexuses become involved, causing intestinal paralysis. The result of this is constipation or complete obstruction of the bowels, and the gas, formed by the decomposition of the intestinal contents, produces distension of the gut, *meteorism* or *tympanites*. Hence the danger of giving opium, which increases these dangers. *Tympanites* raises the diaphragm so that the heart and lungs work with difficulty.

In peritonitis the least *pressure*, even of the bed clothes, is *painful*, hence the patient lies with the shoulders raised and the knees drawn up, to relax the abdomen. The abdominal walls are rigid and board-like and the diaphragm is kept quiet to prevent movement of the viscera, respiration being pectoral. In *colic*, on the other hand, pressure relieves the pain and the lax abdominal walls can be freely moved over the bowels.

**The visceral peritoneum**, besides covering the intraperitoneal viscera, forms folds known as the *mesenteries* and *false ligaments* to attach these viscera to the parietes. The visceral and parietal layers of the peritoneum are continuous by means of these folds, some of which deserve especial notice.

**The great omentum** is the elongated *mesentery of the stomach* which is connected with its great curvature, or attached margin, and descends as an apron in front of the bowels, which it separates from the abdominal walls. In well-nourished persons it often contains considerable fat, which acts like a cholera band in maintaining an even temperature of the bowels. *In the embryo* the omental fold of the *mesogastrium* consists of four peritoneal layers which adhere together in infancy and thereafter appear to consist of two layers containing fat and blood vessels between them. The lesser omental sac extends down between

the two anterior and the two posterior omental layers before they adhere together. The under layers as they pass up in front of the transverse colon and then back to the parietes, become adherent to the colon and to the upper layer of its mesocolon. The portion of omentum extending from the great curvature of the stomach to the anterior surface of the transverse colon, to which it is attached, forms the **gastrocolic ligament or omentum**. It and the transverse mesocolon prevent our reaching the posterior surface of the stomach without passing through one or the other of them. When we pull down the omentum the transverse colon and stomach are pulled down and the former may be seen through it; and when we turn up the omentum we see the transverse colon attached to it. Hence the omentum may be used to find both the stomach and the transverse colon.

The omentum extends down a variable distance into the iliac and hypogastric regions, hence it is very apt to be *found in herniae* as an epilocele. This is said to be more common on the left side because the omentum is more developed on this side. It may be the only content of a hernia, especially in cases of femoral herniae and it is almost constant in umbilical herniae, except in the congenital variety (see umbilical hernia).

The omentum generally *contracts adhesions to the sac* of a hernia in which it is present, provided the hernia is not kept reduced. Such herniae thus become *irreducible*, and the omentum may form a kind of second sac about the gut and often grows into a large conglomerate *fatty mass*, connected with the rest of the omentum by a narrow pedicle passing through the neck of the sac. When the omentum in a hernia is fit to be returned to the abdomen the intestine, if present, should be reduced first.

As a result of inflammation the omentum may contract *adhesions* to contiguous parts and so *form bands* beneath which, as well as beneath adhesions to a hernial sac, the bowel may be caught and strangulated. *Strangulation* may also occur through *holes or slits* in the omentum. Omental adhesions may, under certain conditions, exert such a traction upon the stomach and colon as to produce functional disturbance. A benign effect of omental adhesions is seen where they help to limit inflammatory or hemorrhagic extravasations, or to occlude a perforation of the bowel due to disease.

The omentum, or sometimes a separated piece of it (*omental graft*), is occasionally similarly employed by the surgeon to fortify an intestinal suture, by being fastened over or around the latter. By means of adhesions with ovarian tumors the latter may be supplied with blood through the omentum, in case its blood supply is cut off by the twisting of the pedicle.

From its exposed position *wounds* of the omentum are common. It may plug a small abdominal wound and prevent the escape of other parts. After laparotomy it is well to replace the omentum over the bowels, when there is no contraindication, so as to obviate intestinal adhesion in the line of the cicatrix.

**The small omentum**, extending from the transverse fissure of the liver to the small curvature of the stomach, helps to *bound* the lesser peritoneal sac in front. Its *right border* extends a variable distance on to the first portion of the duodenum, where it is called the **hepato-duodenal ligament**. The latter *bounds* the foramen of Winslow in front and *contains* between its two thin layers the portal vein, the hepatic artery, and the common bile-duct, the vein lying behind the other two, of which the bile-duct is to the right of the artery. Its left extremity encloses the œsophagus.

**The mesentery** is attached to the posterior abdominal wall for about six inches. This *attachment commences* at a point to the left of the second lumbar vertebra, on a level with the attachment of the lower fold of the transverse mesocolon, the end of the duodenum, and the lower border of the pancreas, and *extends* thence obliquely downward and to the right, with a slight convexity to the left, to the right iliac fossa or to the right sacro-iliac articulation. This attachment is secondary or acquired, its real attachment is mesial and about the origin of the superior mesenteric artery, as in mammals below man. Occasionally too in man we find the embryonic type of the single median mesentery for the entire bowel.

At its lower end the *right layer* is continuous with the peritoneum covering the ascending colon, and its *left layer* with the mesentery of the appendix. It forms a posterior longitudinal *partition* in the peritoneal cavity, and its *oblique course directs* hemorrhagic or other extravasations on the right side of the abdomen first into the right iliac fossa and on the left side into the pelvis. Hence the greater frequency of collection of blood in the right than in the left iliac fossa.

Between its two layers are *contained* blood and chyle vessels, nerves, fat in varying quantity and lymphatic nodes, the latter especially near its attached border. In addition a band of fibrous tissue and plain muscular fibers, descending from the left crus of the diaphragm to the end of the duodenum, passes down between the layers of the mesentery and is of sufficient strength to support the weight of the intestines as well as to resist the pressure of the descent of the diaphragm. The name *suspensory muscle of the duodenum and mesentery* is suggested by Lockwood for this muscle. Like the omentum the mesentery may contain *tumors* of various kinds.

**The length** of the mesentery, from its parietal to its intestinal attachment, varies in different parts. It affords great *mobility* to the small intestine, allowing it to be displaced by tumors, etc. Its *average length* is eight to nine inches, which it reaches not far below its upper end.

That part which is connected with the intestine between points six and eleven feet below the duodeno-jejunal junction attains its *greatest length*, *i. e.*, ten inches (Treves). This part of the intestine, as well as the lower ileum, is thus permitted to lie in the pelvis. According to Treves, when the mesentery is normal in length, no part of the small intestine can be dragged onto the thigh through the femoral caudal (artificially enlarged) or into the scrotum through the inguinal

canal, and no coil of intestine can be drawn out of the abdomen below a horizontal plane passing through the pubic spine. But Lockwood states that it is quite common in the adult to find that the small intestines will pass  $1\frac{1}{2}$  inches beyond the right crural arch, up to the left crural arch, and one inch below the pubis. *Herniæ* in which the bowel occupies positions beyond the normal are common and *require*, therefore, a *lengthening of the mesentery*. Whether this is always acquired, or may sometimes be congenital, has not been definitely determined. According to Lockwood the mesentery is relatively longer in infancy, but rapidly decreases after the second year. The length of the mesentery is an *important factor* to be taken into account *in the production of hernia*. The position of the mesentery allows intestinal hernia more freely on the right than on the left side.

The mesentery may contain *slits*, generally due to injury, or *round holes of congenital origin*, through which the intestine may be strangulated. The round holes are in an oval area of the mesentery of the lower ileum, included within an anastomotic arch between the ileo-colic and the last intestinal branches of the superior mesenteric artery, which is often devoid of fat, lymph nodes and visible blood vessels, and is so atrophied that a knuckle of gut might easily be forced through it.

The mesentery is an excellent *guide* to lead us to either end of the small intestine, as in searching for intestinal lesions. Holding up a loop of the intestine vertically we trace its mesentery back to its parietal attachment to make sure that it is not twisted. Assured that the mesentery is not twisted, we follow the intestine upward from the upper end of the loop to find the duodeno-jejunal junction, and vice versa to reach the lower end of the ileum.

The **transverse mesocolon** is three to four inches *deep* and, with the transverse colon, reaches from the posterior to the anterior abdominal wall except at the sides of the abdomen. It forms an imperfect *transverse septum* between the lower part of the peritoneal cavity, containing the small intestine, and the upper part containing the liver, stomach, and spleen. To a certain extent and for a time it may limit a peritonitis on one side from extending to the other. This protection is also increased by the omentum which is attached to the colon above and descends over the front of the bowels. The transverse mesocolon *bounds the lesser peritoneal sac* below, so that in order to reach the posterior wall of the stomach, to expose an ulcer on this surface as well as to do a posterior gastroenterostomy, we divide the mesocolon vertically or parallel with its blood vessels.

The **lesser peritoneal sac**, between the stomach and small omentum in front and the pancreas, etc., behind, *extends* on the left to the spleen and the left kidney. It *opens into* the general peritoneal cavity by the *foramen of Winslow*. The latter normally admits two fingers and through it an internal hernia may pass and become strangulated (Rokitansky, Blondin). This opening may become narrowed or closed and, in the latter case, a kind of cyst may be formed, according to Malgaigne and Begin.

## THE ABDOMINAL VISCERA.

### The Stomach. (Figs. 71, 72, 74, 75.)

The shape of the stomach is like that of a pear, bent near its smaller end. The *œsophagus* opens into it at the right side of its larger end, so that the latter projects, as the *fundus*, about three inches to the left of and one to two inches above the œsophageal orifice, while the *pylorus*, or the opening into the duodenum, is at the smaller end. Therefore the length of the lower or left border is the greater, hence the name **greater curvature**. The **lesser curvature**, the upper or right border, measures from three to five inches and is only one fourth the length of the greater curvature. The great curvature is convex until we approach the pyloric end where there is a slight indentation, between which and the pylorus there is a slight bulging, the *antrum pylori* (or pyloric portion). The lesser curvature is concave except over the antrum, where it is slightly convex.

The *pylorus* can be seen as a slight constriction and *felt* as a thickening. It is the narrowest part of the alimentary canal, having a diameter of one half inch, hence many objects may be swallowed which cannot pass the pylorus and must be removed from the stomach by *gastrotomy*. This is especially common among lunatics, and the number and variety of articles swallowed by them is remarkable, embracing forks, spoons, nails, pebbles, buttons, coins, keys, etc. Teeth plates are not uncommonly swallowed accidentally. It is also remarkable in some instances how large an object can be swallowed and pass the pylorus, *i. e.*, coins, buttons, nails, door keys, metal pencil holders  $4\frac{1}{2}$  inches long, etc. Needles swallowed find their way through the stomach and bowels and appear at various points in the body. The pylorus is liable to *obstruction* or *stenosis* from several causes. The *antrum pylori* is elongated so that it resembles the intestine, especially in the female.

The *cardiac* (or *œsophageal*) *orifice* is so called from its close relation to the heart. The *two surfaces* lying between the two borders are nearly symmetrical and look ventrally and dorsally. The *shape changes with age*; thus some say that it is nearly cylindrical at birth and that the fundus, although it grows rapidly in the first year, does not attain full development until late in childhood. Foetal stomachs, however, may possess a well-developed fundus. In the female the stomach is relatively narrower. No definite senile changes occur. The *shape varies with the degree of distension*. In full distension the fundus and vertical portion are most affected. In the empty state the surfaces are flattened and in apposition. During digestion a *constriction* occurs near the middle of the stomach, almost completely separating the cardiac and pyloric halves. In some cases the fundus may appear more spindle-like and the pyloric half cylindrical, from the uniformly active contraction of the stomach wall. This is probably the normal shape of the empty stomach during life. We can attach no *clinical significance* to the general shape of the stomach except to

PLATE XXXV.

FIG. 71.

Outline of the abdominal viscera, showing their position with relation to one another, the ribs and vertebræ. (Merkel.)

abnormalities, such as those due to diverticula, bands and scars, and *hourglass-contraction*. The latter may be either pathological or, rarely, congenital in origin. Diverticula are very rare.

The size of the stomach varies with the age, sex, and degree of distension as well as in certain pathological conditions. The average capacity at birth is  $1\frac{1}{2}$  ounces; at three months,  $4\frac{1}{2}$  ounces; at six months, 6 ounces; at twelve months, 9 ounces; at eighteen months, 12 ounces. In the adult its average capacity is five pints ( $2\frac{1}{2}$  liters), though it may hold perhaps four liters without being pathologically enlarged. But according to Ewald, its normal limit of capacity is only 1,600 to 1,700 c.c., and it cannot be distended by more than 100 c.c., in addition to this. In *gastrectasis*, or dilatation of the stomach, the capacity may be much increased. Dilatation of the pyloric portion is very rare.

Normally when full its *oblique or longest diameter* measures 25–30 cm., its greatest *vertical diameter* (at the cardia) 15 cm., its *antero-posterior diameter* 10–12 cm. at the fundus and 3–4 cm. at the antrum pylori. The distance between its two orifices varies from three to six inches. When empty and uniformly contracted it is scarcely larger in diameter than the transverse colon. In the female the stomach is smaller than in the male. The weight of the stomach is about  $4\frac{1}{2}$  ounces.

The position of the stomach varies more than that of any other viscous owing to its mobility and varying size. It lies in the left hypochondrium and the epigastrium, the fundus being in the former the rest of the stomach in the latter region. Only in occasional instances does it extend into the right hypochondrium.

The *cardiac orifice* is found behind the seventh left costal cartilage, one inch from the median line, to the left side of the tenth, or eleventh thoracic vertebra, and  $4\frac{1}{2}$  inches from the anterior belly wall. Occasionally the cardiac orifice is found in the median line or even somewhat to the right of it. I have found it in this position in a case of gastrostomy for oesophageal stenosis, and other cases are reported. This orifice is nearer the anterior than the posterior surface of the stomach by one third of its antero-posterior diameter. It is distant  $15\frac{1}{2}$  to 16 inches from the incisor teeth.

The *fundus* extends 3–5 cm. higher than the cardiac orifice and corresponds to the superior border of the sixth rib, and sometimes to the fifth rib, in the left anterior axillary line, to the sixth left chondrosternal joint, and to the ninth or tenth thoracic vertebra. Its highest part lies directly beneath the left dome of the diaphragm, behind and above the apex beat of the heart. Its close relation to the left lung and the heart explains the interference with their function when the stomach is distended, as with flatulence, which causes shortness of breath and palpitation of the heart. Many imagine they have heart disease when the real trouble is indigestion. Owing to the position of the fundus the stomach is sometimes wounded in wounds of the lower part of the pleural cavity involving the diaphragm.

The great curvature in its upper or left part is covered by the diaphragm, which separates it from the lung, the sinus of the pleura and

the thorax as we follow it from above downward. It crosses the left costal margin about the junction of the ninth and tenth costal cartilages. Inferiorly it extends to a point 2 to 4 cm. or two fingers' breadth above the umbilicus, and further to the right it ascends along the median edge of the gall-bladder. A normal stomach fully distended may even reach to the umbilicus, and in cases of *gastrectasis*, or abnormal enlargement of the stomach, the great curvature may reach any level between its normal position and the symphysis. This condition is *due to an obstruction at the pylorus* from cancerous new growth, cicatricial stenosis following an ulcer, or thickening of the circular muscle of the pylorus in some forms of dyspepsia with hyperacidity. The enlargement can be readily *made out by inspection, palpation, and percussion* after distending the stomach with air, by a bicycle pump attached to a stomach tube. The great curvature may also reach a *low level* in *gastrophtosis*, or a downward displacement of the stomach. This condition is not unlikely at times more of a vertical enlargement (without the transverse) than a displacement. The stomach may be somewhat pulled down by the traction of the omentum adherent to the sac of a hernia.

On the other hand when the stomach is *entirely empty*, as in cases of stricture of the oesophagus, the stomach is *high up* under the left lobe of the liver and the costal cartilages and far back in the abdomen, so that the transverse colon projects up in front of it from below and (according to Sébillot) the anterior border of the spleen overlaps it from the side. In such cases it may be hard to *find*, but this can be done (1) by following up the under surface of the liver to the small omentum, and down the latter to the stomach, or (2) by pulling down the omentum and following it up to the stomach over the colon, which we distinguish by the longitudinal bands and the appendices epiploicae. On account of its position the stomach is much less exposed to injury when empty and the injury is less dangerous, because of the little extravasation of its contents.

The **lesser curvature** lies under cover of the left lobe of the liver except in cases of gastrophtosis, when it is displaced below it. It descends nearly *vertically* in front of the left crus of the diaphragm and the left side of the last two thoracic vertebræ, from the oesophageal orifice to the antrum, where it turns quite sharply and passes transversely to the right at the level of the first lumbar vertebra, and then slightly upward to the pylorus. Three fourths or four fifths of the stomach lie to the left of the median line.

The **pylorus** is *covered by* the quadrate lobe of the liver 3–4 cm. to the right of the median line and 7 cm. lower than the cardiac orifice or the sterno-xiphoid articulation. It is more *mobile* laterally than vertically and its radius of mobility is 2–3 cm. It *lies* near the median line, in line with the right border of the sternum when the stomach is empty; further to the right (3 inches according to Braune) when it is full. In general it *corresponds to* a point near the end of the eighth right costal cartilage, to the level of a line drawn between the bony

ends of the seventh ribs in front, and to the upper border of the first lumbar vertebra (or the twelfth thoracic spine) behind. The difficulty of palpating tumors of the pylorus is explained by its being covered by the liver, except occasionally when it is displaced downwards by the new growth before the latter gives rise to adhesions. The *antrum* extends further to the right than the pylorus itself.

From the above facts we gather that the *axis of the stomach* is *more vertical* than formerly supposed. Down to the antrum it is nearly vertical and this fact, perhaps combined with more or less gastrophtosis or gastrectasis, accounts for the sword-swallowing feats. The axis of the stomach is sometimes more vertical in infants, retaining some of the vertical position of the embryo, and in some cases it remains so in the adult.

The anterior surface of the stomach is in *contact with* the diaphragm and the anterior thoracic wall, which covers the fundus; to the right of this, with the liver above and the abdominal wall below. The liver covers the pylorus and the parts just below the lesser curvature, and leaves a more or less triangular area where the stomach is *in contact with the abdominal wall*. This triangle is *bounded* on the left by the eighth and ninth costal cartilages; on the right by the free margin of the liver, passing from the ninth right to the eighth left costal cartilage; and below by the transverse colon, or a line joining the tips of the tenth costal cartilages.

*Through this triangle* we reach the stomach in the various operations on that viscous. The *incision* may extend above the right border of the triangle for the free margin of the liver can be retracted upward. The *line of incision* may be vertical, in the median or semilunar lines or through the rectus muscle, or oblique, parallel with and an inch from the left costal margin. In the latter case the part of the incision external to the rectus divides the three flat abdominal muscles. Behind the rectus we meet with the superior epigastric artery, which we avoid or ligate. Of these operations the most important are *gastrotomy*, *gastrostomy*, *gastroenterostomy*, *pyloroplasty* and *pylorectomy*.

In *gastrotomy* the stomach is opened anteriorly to remove foreign bodies, to treat a stricture of the oesophagus by retrograde dilatation, or for exploration.

In *gastrostomy* a *gastric fistula* is established in order to feed the patient when there is a cancerous stricture of the oesophagus. The many recent modifications of the technique of gastrostomy have aimed at *preventing leakage* of the stomach contents. This is more or less perfectly secured in v. Hacker's method, by using the separated fibers of the rectus as a sphincter, in Witzel's method by making a long oblique fistula surrounded by the muscle of the stomach wall, in Kader's and Senn's method by inverting a small cone of the stomach wall as a valve, etc.

In *gastroenterostomy* an *anastomosis* is made between a low point in the stomach and the upper part of the *jejunum*, when the outlet of the stomach is obstructed. Though formerly done through the *anterior*

*stomach wall*, it is now most often done through the *posterior wall* to avoid the reflux of bile and the vomiting which may follow the anterior method. But if the anastomosis occupies the *most dependent position* it probably makes little difference whether it is anterior or posterior. The *posterior wall* is reached through an opening in the transverse mesocolon, and a Murphy button is commonly used to make the anastomosis. When done for non-malignant conditions the good results are permanent.

**Pyloroplasty** is employed in cases of pyloric stenosis, and the pyloric opening is enlarged by suturing a longitudinal incision in a transverse direction.

**Pylorectomy** has been employed, since its introduction by Billroth, in cases where a cancer of the pyloric end of the stomach is removable. The large opening left after resection of the tumor is closed until it corresponds in size to the duodenum, or altogether closed and a gastro-enterostomy added.

**How is the Stomach Held in Position?**—The stomach is *attached only* at the cardia, the pylorus is fastened to the posterior abdominal wall through its connection with the duodenum. The stomach is also *supported by* the gastrophrenic ligament from the diaphragm, to the left of the oesophagus, and by the lesser omentum from the transverse fissure of the liver. The thickened right border of this omentum extends on to the first part of the duodenum as the hepato-duodenal ligament and helps to support the pylorus. The cardia and pylorus are the most fixed points, and the lesser curvature, attached at either end to these fixed points, cannot change its relative position to any extent, hence it is the more fixed border of the stomach. It moves slightly with respiration. In the gradual distension of the stomach by gas, not by water, the anterior surface becomes more superior by a rotation on the lesser curvature as an axis, which brings the greater curvature upward and forward. When full the stomach rests upon the transverse colon and mesocolon, so that the latter and the hepatocolic and phrenocolic ligaments, which help to support the colon, assist in supporting the stomach. The stomach is not supported by intra-abdominal pressure.

The stomach is also *connected with other structures*. At the great curvature the peritoneum covering the front and back surfaces of the stomach meet and pass down as the great omentum. This is the original mesentery of the stomach. Its left extremity, the gastrosplenic omentum, connects the stomach with the *spleen* and inferiorly the portion known as the gastrocolic ligament connects the stomach with the *transverse colon*.

**Other relations of the stomach.** The *posterior surface* of the stomach *rests in* great part on the transverse mesocolon, above this on the pancreas, with the splenic vessels along its upper border, more to the left on the splenic flexure of the colon, the upper half of the left kidney, the entire left suprarenal capsule, and the anterior surface of the spleen. In addition the crura of the diaphragm, the aorta, the vena cava inferior,

the fourth portion of the duodenum and the solar plexus also lie behind the stomach. Between the pancreas, kidney, and suprarenal capsule behind, and the stomach in front lies the *lesser peritoneal sac*. *Perforating ulcers* of the posterior wall of the stomach may open into this sac or, after adhesion, into one of the viscera named as lying behind it, causing perhaps an abscess of the organ so invaded. Cases are recorded where such ulcers have given rise to ulceration of the splenic artery, causing a fatal hemorrhage into the stomach. On cross-section of the abdomen the stomach is seen to lie between the liver and the spleen, so that it may be displaced by enlargements of either of these organs.

**Layers of the Stomach Wall.**—*Peritoneum* covers the entire stomach except for a narrow strip along the lesser and greater curvatures, where the anterior and posterior layers are continuous with the small and great omenta respectively, and where the vascular trunks run. This serous layer is closely bound by a scanty subserous tissue to the thick muscular layer. Only in a distended stomach does the peritoneum retract somewhat on incision. The *muscular tissue* is quite thick, so that in suturing there is more for the sutures to hold to and less danger of the needle penetrating all the coats than in intestinal suture. Owing to the difference in direction of the fibers of the three layers and of the line of their retraction on division, *gastric wounds* are *ragged* and not likely to gape. If small they may be quite effectually plugged by the protrusion of the mucous membrane, which is permitted by the looseness of the *submucous tissue*. The latter also allows the *mucous membrane* in an actively contracted stomach to form prominent longitudinal folds, more marked toward the pyloric end and along the great curvature, which greatly reduce its lumen. In a moderately contracted stomach slight folds are seen bounding irregular shallow depressions. The latter may partly or wholly disappear when the stomach is relaxed. There is a *zigzag line* encircling the cardiac orifice on its inner surface opposite the tenth thoracic vertebra, where the thick columnar epithelium of the gastric mucosa joins the thinner squamous epithelium of the œsophageal mucosa.

**Vessels.**—The arteries, derived from the gastric, hepatic and splenic branches of the celiac axis, run along both curvatures of the stomach and from both ends, anastomosing where they meet. Branches pass from these trunk vessels, at right angles to the trunks and to the axis of the stomach, over both surfaces where they anastomose on meeting. The veins take the same course. Hence an *incision* parallel with and near the curvatures divides many of these branches where they are largest, and considerable hemorrhage results. Near the curvatures incisions at right angles to them (*i. e.*, parallel with the vessels) cause less bleeding, while midway between the curvatures incisions parallel with them occasion but little hemorrhage. If the larger trunk vessels are concerned in a gastric ulcer and become adherent to the stomach wall and finally eroded, serious hemorrhage into the stomach may result. The veins empty into the *portal vein* either directly or through

the splenic and superior mesenteric. Hence the varicose gastric veins and the *congestion of the stomach* with hemorrhage into it, in cirrhosis of the liver, or cardiac disease accompanied by portal obstruction.

The **lymphatics** of the stomach form a superficial or subserous, and a deep or submucous set. These empty into vessels, with an occasional small node, along both curvatures of the stomach. Those on the lesser curvature run toward the cardia and empty into lymph nodes there, those on the great curvature accompanying the gastroepiploic arteries run into the lymph nodes above the pancreas on the right side, and into those at the hilum of the spleen on the left side. This distribution is to be borne in mind in searching for the metastatic growths of gastric tumors.

**Nerves.**—The *anterior and posterior gastric plexuses*, formed by the left and right pneumogastric nerves respectively, together with branches from the sympathetic, lie near the *lesser curvature* at its cardiac end. The *sympathetic fibers* from the celiac plexus accompany the gastric artery to and along the lesser curvature as the coronary plexus. They anastomose with the pneumogastric fibers and supply largely the pyloric half of the posterior wall. It will be noticed that the plexuses are along and near the lesser curvature especially at its cardiac end, explaining the reflex palpitation of the heart, faintness, or asthma which may occur after going to bed with the stomach full of an undigested meal, which then presses against the lesser curvature and irritates the nerves. After vomiting the attack subsides. Irritation of the gastric pneumogastric filaments may be misinterpreted by the brain as an irritation of the pulmonary fibers and give rise to a "stomach cough." Irritation of the pneumogastric filaments in the neck, brain or stomach (from disease, concussion, or in a sea voyage) may cause vomiting.

**Congenital malformations** of the stomach are rare. It may be displaced in cases of transposition of the viscera and of congenital deficiencies of the diaphragm or anterior body wall. Complete congenital atresia of the pylorus is very rare, stenosis of the pylorus is more common. In certain cases *hourglass-contraction* is probably of congenital origin, in most cases it is due to cicatricial contraction following ulcer or corrosive poison, and it is very much more common in females than in males.

The **pathological conditions** affecting the anatomy of the stomach are chiefly *ulcer and cancer*. **Ulcer** occurs along the *lesser curvature* in 33.6 per cent.; on the posterior wall in 29.6 per cent.; at the pylorus in 12 per cent.<sup>1</sup> Occurring so often on the lesser curvature, *pain* does not come on so quickly after a meal as in case of gastric catarrh, where the great curvature is chiefly involved, for pain occurs only when the food is in contact with the ulcer, hence vomiting brings relief. Gastric ulcer is usually single and varies in size from a 5 cent piece to that of a quarter of a dollar. It is liable to perforate through the stomach and give rise to a circumscribed abscess, if adhesions take place, otherwise to a

<sup>1</sup> Welch's analysis of 793 cases.

general peritonitis. The *cicatricial contraction* following an ulcer at the pylorus narrows the orifice and causes *pyloric obstruction*. This causes at first a hypertrophy of the stomach, to overcome the obstruction, but later on this gives place to dilatation and its sequelæ. An *hour-glass-contraction* may result from the cicatricial contraction if the ulcer occurs in the body of the stomach. *Adhesions* to contiguous viscera may cause violent gastralgias owing to the traction on the stomach. Seventy-five per cent. of *cancers* of the stomach are of the scirrhouss form, and this variety affects the pylorus in sixty per cent. of the cases, where sooner or later it usually obstructs the orifice with the resulting sequelæ. *Lymphatic infection* is said to be less frequent and less rapid than in cancer elsewhere.

*Stricture of the pylorus* may also be due to the pressure of tumors external to it, or to hypertrophy of the circular sphincter fibers, resulting from dyspepsia with hyperacidity which causes a violent and long-continued contraction of the pylorus. In *diaphragmatic hernia* I have seen the stomach in the left pleural cavity, and many such cases are recorded. A part of the stomach may occasionally be found in an *umbilical hernia*. The stomach may be *ruptured* by a contusion. There is more danger of this when the stomach is full and hence in closer contact with the abdominal wall.

**Vomiting** is *effected* by the abdominal muscles compressing the stomach against the liver and diaphragm. The latter is depressed to its lowest level by a full inspiration and fixed by the closure of the glottis, so that a patient with an opening in the trachea cannot vomit. As vomiting is naturally easier with a full stomach plenty of warm water should be given with an emetic. *Eruption* is accomplished by the muscular action of the stomach alone.

### The Small Intestine.

The small intestine, extending between the pyloric and ileocecal valves, *averages in length* in the adult, independently of height, weight or age,  $22\frac{1}{2}$  feet in the male and  $23\frac{1}{2}$  feet in the female. In the infant at birth it averages  $9\frac{1}{2}$  feet. The *diameter* decreases from its upper to its lower end, from  $1\frac{1}{2}$  or 2 inches in the duodenum to  $1\frac{1}{4}$  inches in the lower ileum.

**The duodenum** (Figs. 71, 72, 74, 75 and 77) or first portion, is the only part having a fixed position or extent (ten to twelve inches). It *lies* in great part retroperitoneally. In *shape* it forms a kind of spiral within which is the head of the pancreas. Its natural *division* into three or four parts is useful in studying its relations.

The **first part** (or superior longitudinal portion) is about two inches long and is the most *movable* part on account of its peritoneal relations. Its entire anterior surface, and the first inch or so of its posterior surface next to the pylorus, are covered by peritoneum derived from the right end of the lesser omentum. This is known as the *ligamentum hepato-duodenale* and is continuous with the peritoneum of the stomach. Thus this portion of the duodenum is allowed to follow the movements

of the stomach, and so avoid undue traction. The *direction* of this segment is nearly horizontal and varies with the fullness of the stomach. When the stomach is distended and the pylorus is pushed over to the right it passes nearly directly backwards. When the stomach is empty its course is nearly transverse from left to right, with only a slight inclination backward, and between these extremes its direction varies according to the condition of the stomach. Its *distal end* is fixed at the level of the first lumbar vertebra, under the quadrate lobe of the liver, or the neck of the gall-bladder, so that it is found stained by bile at a post-mortem. It forms the lower boundary of the foramen of Winslow. The common bile-duct, the vena portæ and the hepatic artery pass *behind it*; the head of the pancreas lies *below it*.

FIG. 72.

Abdominal viscera from in front, after His' models.

Behind the neck of the gall bladder it bends downward into the **second part**, which *descends* for nearly three inches to the right of the first, second, and third lumbar vertebræ and in front of the renal vessels, the vena cava and the inner edge of the right kidney. These relations are to be borne in mind in operations on the right kidney. About its middle it is crossed in front by the attachment of the two layers of the transverse mesocolon, between which it is entirely bare of peritoneum and nearly in contact with the right end of the transverse colon. The parts of the second portion above and below the mesocolon are covered with peritoneum in front only. This peritoneum is continuous, above the mesocolon, with the upper layer of the latter, laterally with that covering the front of the right kidney and mesially with the gastro-colic ligament. Below the mesocolon the peritoneum is continuous with its inferior layer.

The *supracolic portion* is in *contact with* the under surface of the right lobe of the liver, on which it forms an impression (*impressio*

duodenalis) to the right of the neck of the gall-bladder. To the left of it lies the head of the pancreas, and between the two the pancreatico-duodenal artery in front, and the common bile-duct behind. It is bound to parts behind it by areolar tissue, which allows of its easy separation and some change in position of the duodenum in the transverse direction. Downward shifting is entirely prevented by the fixation of the first part by the hepato-duodenal ligament, and in this way any traction on the pancreatic and common bile-ducts, and the resulting functional disturbance, is prevented.

The supracolic portion and the first part of the duodenum are exposed between the liver and the transverse colon by pulling the latter up and the former down, and following the pylorus to the right. Sometimes, on account of a high position of the transverse colon and mesocolon, but little of the duodenum is to be found above them. By incising the peritoneum on the right side of the upper end of the second part we may elevate the gut and reach the lower end of the common bile-duct. The latter, usually in common with the pancreatic duct, enters the duodenum at the end of a papilla on the inner and dorsal aspect of the second portion, about three to four inches from the pylorus.

On the interior of the duodenum at the junction of the first and second portions, is a crescentic fold of mucous membrane, on the inner and posterior aspect. According to Brewer, this fold is permanent, is made prominent by pulling the bend upward, averages 1.9 inches from the pyloric valve and 1.4 inches from the papilla, and may be useful in finding the latter.

**Ulcer of the duodenum**, as compared with gastric ulcer, is uncommon, but the writer has known of a number of cases where perforation has occurred and resulted fatally. Unlike gastric ulcer it occurs more often in males (three to one). Its association with burns and scalds was formerly much emphasized, but is now believed to be very uncommon. Its diagnosis is nearly impossible. The perforations are apt to be about two inches from the pylorus and severe hemorrhage often complicates the case and renders surgical treatment a forlorn hope, although the only one. Cicatrization may result in stricture. *Brunner's glands*, which are said to be the seat of perforating ulcers in cases of burns, are mostly in the upper part of the duodenum, and perforation of such ulcers is apt to be intraperitoneal.

The **third or transverse portion** of the duodenum, nearly five inches long, extends from the right side of the third lumbar vertebra across the latter to the left of the third or second lumbar vertebra, crossing in front of the crura of the diaphragm and the great vessels. It crosses the vena cava where the left renal vein enters it. It is the most fixed part of the duodenum, and is only covered in front by peritoneum continuous with the lower layer of the mesocolon. Where the superior mesenteric vessels, which emerge between it and the pancreas, and the root of the mesentery cross the front of the duodenum, the latter is free of peritoneum.

The fourth, or ascending part, about an inch long, *ascends* in front of the left crus of the diaphragm to the second or first lumbar vertebra, so that the end and the beginning of the duodenum are nearly at the same level. It ends by turning forward into the jejunum at the duodeno-jejunal angle. This part is firmly held in place by a band of fibrous tissue, containing some muscle fibers, that descends from the left crus of the diaphragm and is continued into the mesentery between its folds (*the suspensory muscle of the duodenum and mesentery*, Lockwood). (See Mesentery.) The duodeno-jejunal bend remains unaltered in position no matter how much the stomach and intestines are displaced. *Peritoneum* covers the fourth portion in front and partly at the sides.

In about 50 per cent. of the cases examined, a *fold of peritoneum* is to be found passing from the anterior surface of this portion of the duodenum to the parietal peritoneum on its left side. This fold is the anterior boundary of a *triangular pouch* which lies to the left of the gut and is known as the *fossa duodeno-jejunalis*, or *Treitz' fossa*. Its *apex* is below the bend between the third and fourth portions, the *opening* lies superiorly and admits the tip of the finger and sometimes of the thumb. The fold is the remains of the foetal "*duodenal fold*." The duodeno-jejunal junction actually occupies the fossa. The fossa is exposed by retracting the transverse colon upward and the upper end of the jejunum to the right. It is important as being the starting point of a *retroperitoneal hernia*. This is small at first but, gradually dilating the fossa, the latter may eventually contain nearly the entire small intestine, as in the case reported by Sir Astley Cooper, and in several others observed since.

All parts of the duodenum have been *ruptured* by violence, though this is not common. The duodenum may be *wounded* from behind without opening the peritoneum, owing to its large non-peritoneal surface. Only the first portion has ever been found in a hernia. It will be noticed that the *shape* of the duodenum is not unlike that of a *trap* used in plumbing, and it is not unlikely that it acts as such, preventing the regurgitation of intestinal gas into the stomach.

**The jejunum** (*jejunus*—empty, *i. e.*, the condition in which it is usually found after death) and the **ileum** (*īlēūm*—to twist, *i. e.*, the curved or twisted intestine), lie for the most part inside of the more fixed large intestine. Their *attachment* to the posterior abdominal wall by the mesentery allows of such free motion of the coils on one another that they are well adapted to withstand the effects of pressure and contusion, an important fact, for of all viscera they are *most exposed to injury*.

In consequence of the freedom of motion of the coils of small intestine a definite and *constant position* of the different parts is *not possible*. Yet in general, they are disposed in an irregularly curved manner from the left to right, and the jejunum is largely above the ileum and occupies the umbilical and left lumbar and iliac regions, while the ileum is found in the pelvis, the hypogastrium and the right side. For

directions for following the jejunum and ileum to either end see Mesentery, page 289. Often the coils of the jejunum are arranged transversely, those of the ileum vertically.

Some coils of the jejunum, corresponding to the longest part of the mesentery, are found *in the pelvis*. The terminal coils of the ileum just proximal to the ileoæcal valve are also, as a rule, found in the pelvis. The coils of the ileum and jejunum occupying the pelvis are of interest as they are apt to become involved and adherent in pelvic peritonitis, and would probably be found among the contents of obturator, sciatic and pudendal herniae. The *fœtal pelvis* contains no small intestine, and the amount present in the adult pelvis depends upon the distension of the bladder, rectum and sigmoid flexure, and the size of the female pelvic organs.

The *ileum*, or lowest part, is that most frequently found in inguinal or femoral *hernia*, though the jejunum, from its position in the left iliac fossa, would also be likely to be present in left inguinal or femoral hernia. Hence, theoretically, the symptoms of obstruction would be likely to be more acute in a strangulated hernia on the left side than in one on the right side, because the jejunum is more likely to be present in the former. In this connection we may say that *intestinal obstruction*, or other lesions of the intestine, are more serious the nearer they are to the stomach, and hence are more serious in the jejunum than in the ileum. In obstruction of the jejunum nutrition is interfered with, vomiting commences early and is very frequent, the abdomen is but little distended, the expression becomes quickly pinched and anxious, and the progress of the case is rapid and acute; while in similar lesions of the ileum the reverse is true. The acuteness of the symptoms and the fatality of strangulated umbilical hernia may depend partly upon its liability to contain coils of the upper jejunum.

The ileum, from its position, is more apt to be strangulated by internal bands, holes in the mesentery, etc. The coils of intestine must accommodate themselves each moment to changes in form and position of the peritoneal cavity, depending upon the movements of the diaphragm and abdominal muscles, the filling or emptying of the viscera, the presence of effusions, tumors, etc. Hence the rigid fixity of the abdominal muscles and the absence of diaphragmatic breathing in peritonitis, to diminish the movements of the inflamed peritoneal surfaces. A similar object is sought in the opium treatment of peritonitis by decreasing the peristaltic movements of the coils against one another. Abdominal tumors cause a displacement or change of position of the intestines, which varies with the size and position of the tumor and is useful in the diagnosis of the latter. In like manner the small intestine floats on the fluid in cases of ascites so as to be mostly in front or above, according as the patient is reclining or erect. The upper part of the jejunum and the lower part of the ileum are the most fixed portions, as their mesentery is shorter than elsewhere. But the jejunum, two feet or less from its upper end, is freely enough movable to allow it to be drawn up without tension

over the transverse colon and fastened to the stomach in anterior gastro-enterostomy.

Though the upper two fifths of the small intestine below the duodenum is called the jejunum and the lower three fifths the ileum, there is no definite point where one may be said to end and the other to begin. It is often difficult to tell to which part a given coil belongs when it is exposed by operation or accident, especially if the size or appearance is altered by disease. But between the upper end of the jejunum and the lower end of the ileum there is considerable difference. The diameter of the former is  $1\frac{1}{2}$  inches, of the latter  $1\frac{1}{4}$  inches. The walls of the former are more vascular and thicker, owing largely to the valvulae conniventes which are large and numerous, while they are nearly wanting in the lower part of the jejunum and scanty in the upper part of the ileum. If the intestine is opened and presents a large number of well-developed valvulae conniventes we may infer that the opening is in the upper jejunum, and if few or no valvulae conniventes that it is in the lower ileum. If we look through the empty gut toward a light the lines of the valvulae conniventes can be well seen. The contents also vary in the two parts of the bowel considered, corresponding to the stage of digestion.

In the persistent vomiting of intestinal obstruction or peritonitis, after the stomach is emptied the bowel contents are regurgitated by reverse peristalsis and are vomited. The character of the vomit changes from the sour stomach contents to the bitter bile-laden contents of the upper bowel, and finally the matter may become faecal. Faecal or stercoraceous vomiting usually means vomiting of intestinal contents, though the latter do not really become faecal in odor or character above the lower ileum.

**The Layers of the Intestinal Wall.**—The peritoneal coat is so nearly complete that a wound from without or a perforation from within can scarcely occur without involving it. Between the two layers of the mesentery where they pass onto the bowel, there is a strip of the latter averaging  $\frac{5}{16}$  of an inch in width uncovered by peritoneum. This area is the usual cause of the occasional leakage after enterorrhaphy, for the essential feature of the operation is that the serous coat of both ends of the divided gut should be brought together at all points. In enterorrhaphy or in the use of the Murphy button, or other aids to intestinal anastomosis, the two layers of the mesentery, where they pass onto the bowel, should be carefully brought closely together by suture so as to complete the circle of the serous coat. Loss of substance of a limited area of the peritoneal coat may occur without serious impairment of the strength or function of the part of the bowel involved, though strong adhesions are likely to occur here.

The inner or circular muscular coat is three times as thick as the outer layer of longitudinal fibers, hence a longitudinal *wound* gapes more than a transverse one. Owing to the greater thickness of the longitudinal fibers along the free border of the gut, transverse wounds across this part of the gut gape more than elsewhere. Wounds of the

jejunum gape more than those of the ileum, owing to the greater muscular development of the former. *Minute wounds* of the intestine are closed by the contraction of the muscular coat so as to prevent extravasation. The bowels have been punctured without ill effects in many places to allow the escape of gas when excessive tympanites exists and in abdominal operations to facilitate the return of the intestine within the abdomen. At present, however, fewer and larger openings are usually made and afterwards sutured. Wounds somewhat larger than punctures are plugged by the protrusion of the loose mucous membrane which may or may not prevent extravasation. Treves<sup>1</sup> mentions a stab wound with a small puncture of the ileum which remained closed by such a protrusion of mucous membrane, aided by recent lymph, for four days when fatal symptoms suddenly occurred, and it was found post mortem that an intestinal worm (*Ascaris lumbricoides*) had escaped through the wound and led the way for extravasation.

In **larger wounds** the size of the opening is much *reduced* by muscular contraction. Thus Gross found in longitudinal wounds a reduction in length of one half. The mucous membrane is also greatly everted by reason of the muscular contraction, and this is to be remembered in intestinal suture, for it must be inverted in order to bring the edges of the serous membrane together and thereby secure firm healing of the wound, for mucous membrane does not unite with mucous membrane on its epithelial surface.

In order to secure the healing of intestinal wounds the serous as well as the mucous layers are somewhat inverted by *Lembert sutures*. The latter suture catches up the serous and muscular layers external to the line of the wound, so that the suture punctures do not reach the latter but leave a narrow free strip on either side of it. Thus when the sutures are tightened the strips of the peritoneal coat between the two lines of suture punctures on each side are brought in contact, while the edges are inverted and are also in contact with one another.

The worm-like **peristaltic movements** of the intestine are the result of the consecutive contraction of successive portions of the muscular coat. Abnormally this action may be reversed, as in intestinal obstruction, and force the contents toward the stomach instead of toward the colon and thus produce faecal vomiting.

The **caliber** of the intestine varies with the contraction of its muscular wall. When empty the bowel becomes contracted. It may be distended by accumulated faecal matter or by gas. In septic peritonitis and in some other septic conditions the muscular wall in time becomes paralyzed by septic poisoning. Peristalsis therefore ceases and obstruction follows, while the stagnant faecal matter develops gas which distends the bowel. From the *muscularis mucosae* of sheep comes the "*catgut*" of commerce, so much used in surgery.

The **mucous membrane** is *loosely connected* with the layers beneath so as to permit it to move freely over them. This allows it to become

<sup>1</sup>Surgical Applied Anatomy.

everted, so as to plug a small wound, and to become prolapsed in some cases of artificial anus, thus preventing spontaneous closure.

*Peyer's patches*, occurring principally in the ileum and especially in its lower two thirds, are placed lengthwise of the intestine on the side opposite the mesenteric attachment, and hence are best exposed by opening the gut along the attachment of the mesentery. They are the seat of typhoid as well as tubercular ulcers, the former of which usually extends longitudinally in the axis of the patch, the latter transversely in the direction of the encircling blood vessels. In one case of perforating typhoid ulcer, on which the writer operated, the long axis of the ulcer was transverse.

The vessels of the small intestines *enter or emerge* from the bowel along the narrow strip, uncovered by peritoneum, at the mesenteric attachment. The arteries run transversely from either side, thus encircling the gut. This arrangement of the arteries sometimes enables us to distinguish the intestines from other structures in case of doubt.

The large anastomosing branches, which lie between the two layers of the mesentery, are liable to be injured in stab or gunshot wounds and to give rise to serious hemorrhage.

The veins accompany the arteries singly, and flow through the superior mesenteric into the portal vein. Hence they are affected by portal congestion in some conditions of the liver, and septic infection may be carried by them to the latter from the intestine, sometimes producing abscess of the liver.

The lymphatics form two sets as in the stomach, a deep set in the mucous membrane, and a superficial set in the muscular layer. In the mesentery they are known as chyle vessels on account of the milky fluid they contain. They enter numerous (100–200) lymph nodes between the folds of the mesentery, at and near its parietal attachment, which are subject to enlargement in lesions of the intestine like tuberculosis, enteric fever, dysentery, cancer, etc. In case of enlargement of these nodes the lesion should be sought in the intestine.

The nerves come from the coeliac and superior mesenteric plexuses of the sympathetic, with some fibers from the right pneumogastric. For the connection between the nerves of the intestine and those of the abdominal wall see the latter (p. 251).

**Meckel's diverticulum**, a persistent proximal portion of the vitelline duct, is a blind glovefinger-like pouch having the same layers as the ileum and a lumen continuous with it. It arises from the free margin of the ileum from one to three feet from its lower end. It averages two or three inches in length but may be much larger, and ends in a free cylindrical, conical or globular extremity or in a fibrous band which may connect it, as in foetal life, with the umbilicus, or with other parts. It can *cause obstruction*, when its end is adherent, by forming a bridge beneath which a loop of bowel may be strangulated or by pulling on the ileum at its attachment so as to kink the latter. It occurs once in about fifty cases, has been found in external herniæ and may even give rise to a condition resembling appendicitis.

In operations upon the intestines, or in penetrating abdominal wounds which may involve them, it is to be remembered that they are separated in great part from the anterior abdominal wall by the great omentum. As the omentum is the only thing that intervenes between the intestines and the abdominal wall the *intestines* are much *exposed to contusions* by blows, the effects of which are intensified if received unawares, when the belly wall is relaxed, or if the body cannot bend or yield to the blow. In this way the intestine may be *torn*, *severed* or so *bruised* as to slough subsequently and thus lead to a fatal result. This possibility should be borne in mind in cases of severe abdominal contusions and the prognosis be reserved.

In bullet or stab wounds, penetrating and traversing the abdomen, the intestines almost always receive *multiple injuries*, the number of which varies but is generally greater in those wounds whose course is transverse or oblique, because more coils of intestine are thus met with. Occasionally a bullet or knife may pass among the intestines without wounding them. Several such cases are reported where the fact has been demonstrated by operation, but it occurs in less than two or three per cent. of cases. A bullet whose course passes through near the edge of a piece of intestine makes a larger opening than one passing through the center, and the wound of entrance and exit may be continuous if they lie along the edge of the gut.

Along the ileum as well as the colon *diverticula* may occur, nearly as large as the bowel itself. These are due to a hernial protrusion of the mucous membrane through the muscular coat.

The end of the ileum may slip through the ileocecal valve and become prolapsed into the colon, possibly even to the anus. This is one variety of *intussusception* and occurs mostly among children. It may sometimes be reduced by forced inflation of the bowel soon after it has happened, and before the adjacent serous surfaces have finally adhered together.

**Operations.**—*Laparotomy* or *cæliotomy* applies simply to the procedure of opening the abdominal cavity for any purpose and is referred to under the abdominal wall, p. 253. The bowel may be opened (*enterotomy*) to remove an impacted foreign body, in which case it is sutured immediately; or to make an *artificial anus* above an obstruction, after the intestine is sutured into the wound. The permanent opening of the bowel below an obstruction and its suture into the wound for the purpose of feeding the patient (*enterostomy*), is usually done in the upper jejunum (*jejunostomy*), so that the food may pass through the greatest possible length of intestine, but the operation is not very popular. In *enterectomy* a portion of the bowel is cut out or *resected* for gangrene, tumors, stricture, multiple injuries from bullet or stab wounds and many other causes. In a successful case of closure of sixteen bullet wounds of the small intestine, reported by the writer, three or four inches of the gut were resected, as there were four holes within two inches, the closure of which would have caused a stricture or kinking of the bowel. The successful resection of two

meters of the intestine has been reported, and many cases where more than one meter has been resected.

After resection *intestinal suture* is performed, preferably by the end to end suture or, if it is not possible to bring the ends together without tension, lateral anastomosis may be made after inverting and closing the divided ends. As a palliative operation lateral anastomosis is often made between the coils above and below a lesion without resection of the diseased parts. The *end to end suture* is preferable if feasible, for peristalsis will follow its natural course and there is little or no danger of stricture from contraction of the opening. Various mechanical aids to facilitate both forms of intestinal union and to save time have been devised, among the most perfect of which is the Murphy button. The importance of securing perfect apposition of the opposing peritoneal surfaces throughout, in intestinal wounds or operations, has been referred to above.

### The Large Intestine.

#### Ileocæcal Region.

The **cæcum** (Fig. 73), or blind head of the colon, is the large cul de sac of the colon that lies below the entrance of the ileum. In man and the carnivora it is rudimentary, while in the herbivora and graminivora it is of great size, so that in man it has been called an anatomical protest against vegetarianism. Its *width*, three inches, is greater than its *length*,  $2\frac{1}{2}$  inches, and it is relatively and absolutely larger in the adult.

As to *shape*, *four types* may be distinguished. (1) The *faetal or infantile type* is conical with the root of the appendix at the small end of the cone, where the longitudinal bands are about equidistant. This persists in about two per cent. of cases among adults. In type 2 the appendix still comes off from the lower end at the meeting point of the three bands, but on either side of it the cæcum is expanded into two equal sacculi. It occurs in the adult in three per cent. of cases. Type 3 is the *common or normal form*, occurring in man in ninety per cent. of cases. In it the right sacculus and the anterior wall have outgrown the left side so that they form the lower end of the cæcum while the root of the appendix, to which converge the longitudinal bands, has been displaced upward, inward and backward, to about  $\frac{2}{3}$  of an inch below the entrance of the ileum. The *longitudinal bands* are thus seen to be a uniform and useful guide to the base of the appendix. The anterior band is our best guide to the root of the appendix, for it is the most accessible. Type 4, comprising four or five per cent. of cases, is an exaggeration of 3, in which the root of the appendix is displaced to the inferior ileocæcal angle by the atrophy of the left sacculus.

The cæcum is the most *superficial* portion of the large intestine. When full it *occupies* most of the iliac fossa and is in contact with the anterior abdominal wall, but when empty, as after fasting or when there is obstruction in the small intestine, it is smaller and covered by

coils of the small intestine. Its *normal position* is in the right iliac fossa, on the psoas muscle, above the outer half of Poupart's ligament, with its apex projecting over the inner edge of that muscle and lying a little to the inside of the middle of Poupart's ligament. It may sometimes lie further mesially, extending down into the pelvis or toward or even across the median line. In other cases it may lie more to the right, entirely on the iliæ muscle or with only its apex on the psoas. It is not infrequently *displaced downward* so as to be found in a *right inguinal or femoral hernia*. Such herniæ are provided with a complete peritoneal sac except in rare cases.

The *foetal cæcum* is situated at first within the umbilical region, thence it ascends into the left hypochondrium from which it passes across into the right hypochondrium and then descends into the right iliac fossa. An interesting and important *variation in the position* is that in which it remains undescended from its foetal position above and to the left of the umbilicus, the ascending and transverse colon being absent. More often it is *partly descended* and just below the liver or at any point between the liver and its normal position. Accordingly it may even be found in a congenital umbilical hernia. It is not uncommon to find the cæcum unusually high on the right side, having been arrested in its descent into the right iliac fossa. The writer has met with such cases in operating for appendicitis where the cæcum was above the crest of the ileum. The importance of these irregular positions of the cæcum lies in the fact that the appendix is correspondingly shifted.

The *direction* of the cæcum is not quite vertical but it inclines slightly inward below. If we take as its *upper limit* the lower edge of the ileocolic junction the cæcum is completely covered by peritoneum. The latter, therefore, is first reflected onto the iliac fossa from the ascending colon, so that the subperitoneal areolar tissue of the iliac fossa is never in direct contact with the posterior surface of the cæcum, which is free in the peritoneal cavity. The level of this reflection of peritoneum and of the upper end of the cæcum varies, but is usually about midway between the level of the anterior superior spine and of the highest point of the iliac crest. Quain, Berry and others state that in five per cent. of cases the peritoneum is reflected just below the upper end, leaving the posterior wall of that part connected with the subperitoneal areolar tissue, but they make the cæcum reach a higher level, *i. e.*, that of the ileocæcal valve. The *mobility* of the cæcum depends largely upon the distance between its tip and the reflection of peritoneum posteriorly from the colon, and upon the presence of an ascending mesocolon. A mobile cæcum may even find its way into a left inguinal or femoral hernia. In some cæcal herniæ the peritoneum of the iliac fossa and its reflection onto the lower end of the colon appears to have slid down so as to form part of the posterior wall of the sac.

**Foreign bodies** that have been swallowed and have passed the pylorus are apt to lodge in the cæcum, where they may ulcerate through the

cæcal wall and cause perityphlitis. The largest accumulation of faeces in cases of *faecal impaction* is often found in the cæcum. Hence *stercoral ulcers*, due to the pressure irritation of retained or impacted faecal masses, are more common in the cæcum than in any other part of the intestine. The cæcum, according to Cobbold, is the seat of the *pin worm* (*oxyuris vermicularis*), but others claim that this is lower down in the colon. *Intestinal concretions* are not uncommonly met with here.

In cases of intestinal obstruction the condition of the cæcum may assist us in diagnosis. If the obstruction be in the colon the cæcum will be found greatly distended, while it is normal or collapsed in cases of obstruction of the small intestine. The cæcum is capable of enormous *distension*, if gradually effected, and has been observed larger than the full stomach. Flexing the thigh upon the abdomen will empty a slightly distended cæcum, if normal in position. The *structure* of the cæcum is like that of the colon, the peculiarities of which are described later.

**The ileocæcal or ileocolic valve** guards the entrance of the ileum into the large intestine at the junction of the cæcum and colon. It is normally found on the internal and posterior aspect of the large intestine, but rarely, by a rotation of the latter, the ileum may pass behind it and open on its outer side, or it may open more in front when, occasionally, the posterior part of the cæcum is more developed than the anterior. The valve consists of *two flaps* formed by the invagination of the ileum into the colon. It is composed of the mucosa, submucosa and circular fibers, while the peritoneum and longitudinal fibers pass directly over the angle between the ileum and the large intestine and form no part of the valve. Hence, if the two outer layers are divided and traction is made on the ileum, the valve is unfolded and pulled up into the ileum, which then presents a funnel-shaped opening into the large bowel. The two flaps project nearly transversely into the lumen of the large intestine and this projection is continued from either end of the slit-like opening for a short distance around the circumference of the colon as the *fræna*, or *retinacula*, of the valve, similar to a plica of the colon, so that the valve may be said to open on the summit of a plica.

When the cæcum and colon are distended the flaps of the valve are pressed together, preventing regurgitation into the ileum. In an ordinary high enema the valve renders impossible the passage of the fluid into the ileum, but if a high pressure is steadily continued the fluid may pass the valve, though probably not before peritoneal lacerations and other damage to the large intestine have occurred. Hence practically, for diagnostic and therapeutic purposes, the valve is *not permeable to fluids* from below, and the attempt to force fluids past the ileocæcal valve from below is unsafe and unjustifiable. Some say that high enemata may pass the valve in a considerable proportion of cases, but in these cases the valve is regarded as imperfect and incompetent from the first. With *air or gases* it is otherwise; thus Senn has shown that hydrogen gas inflated into the colon through the rectum, under a pressure varying from one fourth to two pounds, *may safely pass the valve*,

enter the small intestine and disclose a wound of the latter in case of stab or bullet wounds of the abdomen. In such cases the incompetency of the valve depends upon gradual lateral and longitudinal distension of the cæcum which mechanically separates the margins of the valve. The same explanation applies to those cases of intestinal obstruction where there is evidence of the return of the contents of the large into the small intestine, though some deny that it occurs. The baneful effect of forced high injections of fluids as compared with that of gases probably depends upon their weight and lack of elasticity.

**Intussusception**, the invagination or telescoping of one part of the bowel into the part next below it, generally occurs in this region and is most common in childhood, under the age of ten years. The ileo-cæcal form is the commonest and in it the ileum with the cæcum is prolapsed down the colon. The ileocæcal valve forms the *apex* of the intussusceptum, or prolapsed mass, and may even reach the rectum and present at the anus. Rectal examination should, therefore, always be made in cases where intussusception is suspected. In a rarer form, the ileocolic, the ileum is prolapsed through the ileocæcal valve into and along the colon. The valve and cæcum retain their positions while the ileum forms the summit of the intussusceptum. A still rarer form is the colic, where one part of the colon is invaginated into a part below, but the extent of this is limited by the shortness of the mesentery of the colon. The intussusceptum stimulates the enclosing intussuscipiens to painful straining to stool (*tenesmus*) and a discharge of bloody mucus from the anus results. Occasionally the intussusceptum itself is passed, after sloughing.

On section an intussusception is found to consist of *three cylinders* of bowel, two of which belong to the prolapsed part, or intussusceptum, and one to the containing part, or intussuscipiens. A rare form, double intussusception, consists of five cylinders. The *serous surfaces* of the intussusceptum are in contact with one another and are liable to form adhesions. The mesentery is compressed between these surfaces on one side, and this pressure is apt to cause venous congestion and finally gangrene. In such cases the invaginated bowel may slough off and be passed per anum, and a spontaneous recovery result. Between the intussusceptum and the intussuscipiens the mucous surfaces are in contact.

**The appendix (vermiformis)** is a narrow, cylindrical, blind tube, which represents the rudimentary or atrophied lower end of the larger cæcum of many other animals. Even in the human foetus it is seen to be merely the narrowed extremity of a capacious cæcum. Like other *vestigial parts* it is prone to *inflammation*, which tends to cause its *obliteration*, a process which evolution would appear to be slowly bringing about.

Its *length* varies between 1 and  $9\frac{1}{2}$  inches, and *averages* about 4 inches. It attains its greatest length in early adult life (20–40 years, Berry) after which it shrinks somewhat. Its length bears no relation to the size of the cæcum. In a few authentic cases it has been reported

wanting. When this condition is apparently disclosed at an operation the fact should be accepted with doubt, for its presence may not be apparent without thorough and careful dissection when it occupies certain irregular positions. Its diameter is about one fourth of an inch at the base and one fifth of an inch at the apex, but in old age it may become still smaller. The longer the appendix the greater the difficulty, other things being equal, of egress of a solid or semi-solid body from the distal end. With a long narrow process the conditions are favorable to the stagnation of its contents, which predisposes to inflammation.

The *length and the size of its lumen* is of more practical interest. The *diameter of the lumen* varies in different parts between that of a fine probe and that of a quill and the *average*, according to Ferguson, is that of a No. 9 sound of the English scale. A variable point is the *opening into the cæcum*, ranging from a mere pinhole to a No. 7 catheter (English scale). It is often guarded by a valve or a prominence of mucous membrane due to an increase of lymphoid tissue beneath it. This is especially so in childhood and it may decrease or disappear later. The size of the opening here is important, for a small opening admits fluid faeces and prevents or hinders the escape of semi-solid material. A valve was described by Gerlach, guarding the appendico-cæcal orifice and so directed as to cause retention of the appendical contents, but its existence is now doubted.

In about 25 per cent. of cases the *lumen* is partially, less often completely, *obliterated* commencing with the distal end. It is a *physiological* not a pathological process. Very little (4 per cent.) of this obliteration is found in the first ten years of life, while it is present in over 50 per cent. of cases at sixty years. The obliteration of the lumen at its distal end *shortens it*. The lumen may also be found *stenosed irregularly* here and there, as the result of previous attacks of inflammation (appendicitis), and these stenoses favor recurrence of inflammation by interfering with the proper emptying of the appendix. The presence of obliteration of its lumen can not be told by the macroscopic external appearance of the appendix.

The appendix is held in position (1) by the attachment of its base to the cæcum (see cæcum), (2) by a mesentery of its own (mesenteriolum). The base of the appendix, and with it the appendix itself, *varies in position* with that of the cæcum. Thus it may be unusually high when the cæcum is partly or wholly undescended (see cæcum).

The *mesentery of the appendix* (*mesoappendix* or *mesenteriolum*) is derived from the lower or left layer of the mesentery, along a straight line a short distance below the bowel, and not quite parallel with it. It is *triangular* in shape with its apex at the base of the appendix and one side attached to the abdominal wall, or the mesentery, the other to the appendix, while the base is free. The mesenteriolum does not, as a rule, extend to the tip of the appendix, but only about two thirds of the distance, so that the terminal portion of the latter is either

wholly covered by peritoneum or it possesses a narrow fringe of peritoneum continuous with its mesentery. The appendical border of the mesoappendix is longer than its parietal border, which partly accounts for the tortuous or coiled position of the appendix, similar to that of the small intestine and due to the same cause.

The appendix is therefore an *intraperitoneal organ*, wholly covered by peritoneum except for a narrow strip along the attachment of its mesentery. Hence inflammation of the appendix (*appendicitis*) is an intraperitoneal inflammation, unless walled off by adhesions and plastic exudate. In *exceptional cases* the appendix is in whole or in part *extraperitoneal*. Thus it may lie behind the cæcum, adherent to its wall and covered by its peritoneum, or its distal portion only may be extraperitoneal, behind the colon, while its proximal part is intraperitoneal, or vice versa. Probably some of the cases reported as extra-peritoneal were really instances of the appendix herniated into and adherent to the ileocaecal or subcæcal fossæ.

As a result of inflammation the appendix may contract *adhesions* to the visceral or parietal peritoneum with which it is in contact. These adhesions vary from a single delicate one to those completely binding down the entire length of the appendix. The latter condition is not infrequently found in operating for appendicitis. I have found the tip separated from the rest and only connected with it by scar tissue, representing a necrotic area of the tube. In removing an appendix closely adherent to the posterior parietes and directed inward the relation of the ureter should be borne in mind. Adhesions to the ileum may even form a constricting band about it, or a bridge may be formed beneath which the small intestine may be strangulated.

It is stated (Clado) that in one case in ten in females there is a process of peritoneum passing from the right ovary to the mesoappendix, (*appendiculo-ovarian ligament*) which contains lymphatics and a *small artery* forming an anastomosis between the appendicular and ovarian vessels. It has also been suggested that theoretically this anastomotic circulation would confer a certain immunity against appendicitis, by preventing congestion and avoiding gangrene.

In *position* the appendix, though tortuous, has a *principal direction* from base to apex, and is said to "point" this way or that. It may point in any direction like the needle of a compass or the hands of a watch, and its direction is sometimes indicated by the points of the compass. A great number of observations have been reported as to the direction of the appendix by different observers and with varying results. There are **two main positions** of the appendix, one *upward* behind the cæcum, the other *downward* away from the cæcum. Both of these main positions may be modified by a *lateral deviation* to the right or left. Thus the appendix may point upwards and to the right, and lie to the outside of the cæcum and colon, or it may point upward and to the left, lying below the mesentery and the lower end of the ileum. Again when it points downward it may lie along the pelvic brim or project into the pelvis. The *order of frequency* is (1) retro-

cæcal, (2) pelvic, (3) upward and inward, (4) variable. The up-turned appendix is probably to be explained by adhesion of its distal end in its descent from its foetal position beneath the liver, the down-turned appendix by the absence of such adhesions. It will be observed from the above that the appendix is *mostly in the right lumbar, hypogastric or umbilical regions* and more rarely in the right iliac region, though it usually lies in part or wholly in the right iliac fossa.

Its *curved or spiral course* is due to its short mesentery, or in other words to its growth between points fixed at an early date. The most fixed point is where the postcæcal branch of the ileocolic artery joins it; another fixed point is where the fusion between the non-vascular fold and the posterior vascular fold (mesoappendix) terminates.

The relations of the appendix to the anterior abdominal wall are most important for clinical purposes. Both for diagnosis and operation **McBurney's point** is the one most commonly used. This is where the line between the anterior superior iliac spine and the umbilicus meets the outer border of the rectus, or  $2\frac{1}{2}$ -3 inches from the iliac spine. It lies in the right lumbar region and is a guide to the base of the appendix. In the vast majority of cases the latter will lie somewhere beneath a circle two inches in diameter having this point as its center. Clado locates the guiding point lower down on a line with the anterior superior iliac spine at the outer border of the rectus.

The walls of the appendix present the same layers as those of the cæcum and colon. We have already studied the peritoneal covering. The muscular fibers are largely replaced by fibrous tissue. The existence of *longitudinal muscle fibers* is seen in the rapid shortening of the appendix after removal, sometimes by one third of its length. It is spread out uniformly and not arranged in bands as in the cæcum and colon. The *circular muscular fibers* are demonstrated by the peristaltic movements of the appendix that are sometimes observed, and by their retraction so as to expose the mucosa after lengthwise incisions. This layer may form about one third of the thickness of the appendical wall. The *submucosa* is a thick layer of dense areolar tissue containing many solitary *lymph follicles* which are more abundant here, and in the cæcum, than elsewhere in the large intestine. They are also more numerous in early life up to the twentieth or thirtieth year, after which they normally atrophy more or less. Where the lumen is obliterated the mucous glands of the *mucosa* are found to have disappeared, while the other parts remain. The mucosa is also rich in *lymphoid tissue*. Abundance of lymphoid tissue is a marked feature of the appendix and, like that tissue elsewhere, it is prone to inflammation, especially so in early life when it is in greatest abundance. This corresponds with the known *greater frequency of appendicitis in early life*.

The *distal end* of the appendix is thick and very fibrous. The presence of *fæcal concretions* in the lumen of the appendix is quite common. They may lead to inflammation and perforation of the appendix, but by no means necessarily cause appendicitis, for we often find them

(

## PLATE XXXVI.

FIG. 78.

Cæcum, appendix and end of ileum, with the blood supply and the neighboring fossæ. Somewhat schematic. (Merkel.)

post mortem without sign or history of appendicitis, yet in cases of appendicitis they are present in considerably over fifty per cent. of cases. Although *foreign bodies* may be found in the appendix they are an infrequent cause of appendicitis, as compared with other causes.

The swelling of the mucosa in inflammation tends to narrow or entirely close the lumen at points already narrowed by stenoses, valves or duplicatures of mucous membrane, or by twists or angles in the appendix. As the appendix is contractile but not extensible it is thus put to great strain to expel its contents. The pressure on its wall causes venous congestion and adds to the swelling, and it is a question of overcoming the obstruction or becoming gangrenous. If a concretion is present as an additional obstructing or compressing agent, local gangrene is even more likely.

**Vessels and Nerves.**—The appendix is supplied by the *postcæcal branch* of the ileocolic artery. The main or *distal branch* reaches the appendix by passing along the free border of the mesoappendix, between its folds. The *proximal branch* passes to the root of the appendix. Exceptionally the artery passes directly to the tip of the appendix without branching and then runs back toward its base. In such a case the stasis of its blood current, from pressure, etc., before it branches within the submucosa would involve the entire appendix in gangrene. Local blood stasis due to inflammatory pressure is the cause of local gangrene of the appendix.

The *lymphatics* enter the mesoappendix where a *lymph node* is sometimes present, which may be enlarged or even broken down in appendicitis. They finally pass into those of the mesentery, though occasionally, in the female, they may empty into those of the ovary through the appendiculo-ovarian ligament.

The *nerves* supplying the appendix come from the superior mesenteric plexus which also supplies the small intestine, and the large intestine as far as the splenic flexure. Hence the explanation of the *pain in appendicitis* being often referred at first to some part of the intestines, or to the epigastric or umbilical regions.

**Pericæcal Fossæ.** (Fig. 73.)—There are a number of peritoneal pouches or fossæ in the ileocæcal region which deserve notice because into them the bowel, and especially the appendix, may be herniated.

The upper, or *ileocolic fossa*, lies just above the ileocolic junction and is *bounded* on the sides by the ileum and the colon, and in front by the fold of peritoneum formed by the passage across the ileocolic angle of a branch of the ileocolic artery. It *opens* downward but is too high to concern the appendix and is also less important than the following because it is *smaller* and *less constant*.

The *ileocæcal fossa* is exposed by turning up the cæcum and drawing down the appendix. It is *bounded* on the right by the cæcum, on the left by the small intestine, and lies between the intermediate bloodless ileocæcal fold in front and the mesoappendix behind. It *opens* outward and downward, is almost constant, and is large, admitting two fingers. It sometimes is very deep, extending up behind the ascend-

ing colon as far as the kidney and duodenum. It is to be remembered that the *appendix* is often found in this fossa which makes it of practical importance. The appendix so placed may be thought to be extra-peritoneal or even to be absent, hence we should look for this fossa and feel behind the cæcum and colon when the appendix is not readily found.

The **subcæcal** (or postcæcal) **fossa** is too high to be of clinical importance in appendicitis though the appendix may sometimes be found within it, and be thought to be absent. Its mouth separates the layers of the mesocolon at its lower end.

### The Colon.

The large intestine (Figs. 71, 72, 75 and 77), from the tip of the cæcum to the point where the mesorectum ends, opposite the third sacral vertebra, averages four feet eight inches in *length* in the male, and two inches less in the female. Its **diameter** decreases from above downwards, measuring  $1\frac{1}{2}$  inches in the sigmoid flexure and three inches in the cæcum. It varies with the fullness or emptiness of the gut, which is liable to enormous **dilatation**, if this is gradually produced. The small intestine may sometimes be larger than the large intestine, in obstruction of the bowel. In some cases of intestinal obstruction, situated low down, the faecal accumulation may so distend the colon as to displace the heart and lungs upward and cause shortness of breath and palpitation of the heart, which can be relieved by the removal of the collection of faeces. Dilatation of the colon may occur among rachitic infants, temporarily; or it may be associated with hypertrophy of the bowel wall, constipation and abdominal distension. On the other hand the colon is liable to be the seat of **stricture**. This tendency increases from above downward, being most common at the narrowest part, *i. e.*, the junction of the sigmoid flexure and the rectum, and least common in the ascending colon. The **flexures** of the colon are also a *favorite situation* for stricture. The **percussion note** of the colon is of a higher pitch than that of the stomach, owing to the difference in size and shape.

The **Capacity**.—The colon of an infant six months old holds one pint, that of a child two years old two or three pints, and that of an adult nine pints. It is useful to remember these figures in irrigating the colon. No attempt should be made to force fluid above the large intestine. The irrigation of the colon empties the lower ileum by exciting active peristalsis. The colon is so arranged as to surround the *small intestine* in a circuit from right to left.

The colon is characterized by (1) three longitudinal bands or *tæniæ* separating (2) three rows of alternating sacculi (*haustra*) and constrictions (*plicæ*), (3) the appendices *epiploicæ*. Of the three longitudinal bands or *tæniæ* the one along the anterior surface is the longest and most prominent. As they start from the base of the appendix this anterior band is most useful in helping us to find the latter. They measure about half an inch in width and are about half as long as the actual length of the large intestine. Accord-

ingly they pucker up the intervening intestinal walls into three rows of pouches or *sacculi*, alternating with constrictions, and hence if these bands be dissected off the gut will be made much longer and of uniform contour. They disappear in the lower part of the sigmoid flexure.

Between the three bands the longitudinal fibers are sparingly present, hence the *sacculi* and *plicæ* are made up of all layers. The anterior and inner of these bands are useful in operations in distinguishing the large from the small intestine. As these bands are conspicuous only when covered by peritoneum, the posterior band, being along the attached border, is of little use as a guide in the retroperitoneal lumbar operations (lumbar colotomy, etc.). In cases of very great distension the longitudinal bands, as well as the *sacculi*, are temporarily less noticeable or even effaced. In such a case we can recognize the large intestine by the presence of the third characteristic, the *appendices epiploicæ*. These are small pouches or tassels of peritoneum containing more or less fat and attached to the peritoneal covering of the large bowel, except the lower rectum. They are seen especially along the internal band, and are most numerous in the lower part. They therefore afford no help in seeking for the colon through the loin, along its attached or non-peritoneal area.

Solitary *lymphoid follicles* are most numerous in the cæcum and appendix and occur throughout the large intestine. Hernia-like *diverticula*, usually multiple, may occur throughout the colon and may sometimes lodge faecal concretions.

The large intestine is *palpable* throughout except at and near the flexures which are deeply placed. Hence, save at the flexures, tumors of the colon, even when of moderate size, can be well made out, the progress along the colon of an intussusception can often be carefully watched, as well as the effects of injections of fluid or gas for its reduction. The outline of the colon in cases of faecal accumulation can also be distinctly defined. In *distension* of the large intestine from any cause the front of the belly is comparatively flat, as long as the distension is confined to the large bowel, while the two sides and the region just above the umbilicus are prominent. The reverse is the case in distension of the small intestine.

**Vessels and Nerves.**—The *colic branches* of the *superior mesenteric artery* supply as far as the splenic flexure (the end of the midgut) and there anastomose with the branches of the *inferior mesenteric artery* which supplies the large intestine below this point. The *veins* enter the portal circulation.

The *lymphatic vessels* of the ascending, transverse, and descending colon enter the mesenteric nodes, those of the sigmoid flexure, the lumbar nodes.

The *nerves* are *sympathetic nerves* and accompany the arteries. Those which supply the cæcum, ascending colon, and right half of the transverse colon come through the superior mesenteric plexus from the celiac plexus; while those supplying the left half of the transverse

colon, the descending and the sigmoid colon come through the inferior mesenteric plexus from the aortic plexus.

The ascending colon and descending colon are *vertically placed* in the lumbar and hypochondriac regions along the lateral border of the quadratus lumborum and in front of the lower part of the right kidney and the lower part of the outer border of the left kidney. Hence abscess of the kidney may perforate the colon retro-peritoneally. The *guide to the colon by the lumbar approach* is the *outer border of the quadratus lumborum muscle*, below the kidney. The second portion of the duodenum is also behind the ascending colon. The *descending colon* is *more laterally placed* than the ascending, and hence is more accessible through the loin. The ascending colon averages five inches from the ileocecal valve to the under surface of the right lobe of the liver (*impressio colica*), on the right of the gall-bladder. The descending colon averages  $8\frac{1}{2}$  inches to the iliac crest, the commencement of the sigmoid loop.

A *mesentery* is provided for the ascending colon, varying from one to three inches in length, in only 26 per cent. of cases, and for the descending colon in 36 per cent. (Treves); in the other 74 or 64 per cent. respectively, the peritoneum covers the front and sides only, leaving a wide strip uncovered posteriorly. This strip varies in width, averages one third of the circumference of the colon, and is wider the more distended the colon becomes. It is here that the colon is *opened in lumbar colotomy*, hence the presence of a mesentery is of importance in connection with this operation, especially in the case of the descending colon which is the portion most often opened.

Except when distended the ascending and descending colons lie well back in the flank, covered in front by some coils of the ileum and jejunum. The ascending colon may be absent when the cæcum has not descended, but the descending colon shows but little tendency to variation and is the only part of the gut, below the duodenum, that retains its original position in the great vertical foetal loop of intestine.

The transverse colon averages 20 inches in *length*, but is very variable. As it is longer than a straight line between its two ends it describes a curve *convex forward and downward*. As a rule, it *lies* above the level of the umbilicus, but in 29 per cent. of cases it is below this line, and in some cases it is *displaced downward* in an abrupt V- or U-shaped bend which may even reach the symphysis, while the two flexures are normal in position. Such bends are due to habitual constipation or to congenital causes, according to Treves. In the majority of cases the central portion of the transverse colon is in the line separating the epigastrium from the umbilical region.

**Relations.**—*Above* is the under surface of the liver, the gall-bladder, the great curvature of the stomach, and the lower end of the spleen; *behind* is the second part of the duodenum, the pancreas, and the transverse mesocolon; *below* is the small intestine, and *in front* the great omentum and anterior abdominal wall.

The transverse colon always has a *mesentery* (*mesocolon*) (Fig. 72), which from its length renders this the *most movable portion* of the colon, hence it is often found in the sac of an umbilical hernia. Its anterior surface along the anterior band is *adherent to the great omentum*, which separates it from the anterior abdominal walls. Through the omentum the sacculi of the colon can usually be seen. By raising up the omentum we expose the transverse colon adherent to it. This portion of the colon and the omentum shut in the coils of the small intestine above and in front, respectively. The part of the omentum between the great curvature of the stomach and the transverse colon (*gastrocolic ligament*) connects the two, so that the latter moves with the stomach. It overlies the latter when it is empty, and is pushed down by it when it is full. Many errors in diagnosis are attributable to faecal masses impacted in the transverse colon.

Owing to the close relation of the *hepatic flexure* and the right end of the transverse colon with the gall-bladder, ulceration of the latter, due to gall-stones, has sometimes extended to the adherent colon and the gall-stone has thus entered the colon and been passed per anum. It is often found stained with bile, post mortem. If the gall-bladder and the jejunum or duodenum can not be approximated in cholecystenterostomy, the anastomosis can be readily made with the colon and the short-circuiting of the bile has had no untoward effect on the patient's condition. Hepatic abscess has also ruptured into and been discharged through this part of the colon.

The *splenic flexure*, at the left end of the transverse colon, is in contact with the lower end of the spleen in the left hypochondrium. It lies behind the stomach and is at a higher and more dorsal level than the hepatic flexure.

Both *flexures* of the colon, deeply placed at the back of the hypochondriac regions, are held by bands of peritoneum passing from the hepatic flexure to the transverse fissure of the liver (*lig. hepato-colicum*), and from the splenic flexure to the diaphragm opposite the tenth and eleventh ribs (*lig. phreno-colicum*). The latter, helping to support the spleen, is also called the *sustentaculum lienis*.

The **sigmoid colon or flexure** extends from the level of the left iliac crest to the third sacral vertebra at the end of the mesenteric attachment, including the part formerly called the first piece of the rectum. Including the latter it forms an *Ω-shaped loop* averaging 17½ inches long. The sigmoid flexure is *normally found* in great part in the pelvis and not in the iliac fossa, unless displaced out of the pelvis by its own distension or that of the bladder, rectum, or female pelvic organs, with which, as well as with the small intestine and often with the appendix or even the cæcum, it is in relation in the pelvis. If the mesentery of the sigmoid colon is unusually short, the latter may be very largely in the left iliac fossa. This loop is liable to enormous *dilatation* from faecal accumulation, and has been known to reach up to the liver.

In the newborn the sigmoid loop, usually filled with meconium, may

reach over to the right side owing to its long mesentery. Under such conditions the opening of this loop in the left groin to establish an artificial anus, which is required in cases of congenital deficiency of the rectum, might be difficult. Yet according to Curling, it is found on the left side in 85 per cent. of cases in young infants.

The sigmoid loop is provided with a **constant mesentery**,  $1\frac{1}{2}$  to  $3\frac{1}{2}$  inches long from parietal to intestinal attachment, which connects it with the left iliac fossa. The *line of attachment* of this mesentery crosses the psoas muscle to reach the pelvic brim at about the bifurcation of the left common iliac vessels and the sacro-iliac articulation, or a little above it. Then it turns sharply downward and extends to the middle of the third sacral vertebra. The two attached extremities of this loop are only three or four inches apart and may be nearer abnormally. Hence, since the loop itself is fairly movable, the conditions are such that we can easily see how a twist (*or volvulus*) may occur, as it does, more often in this portion of the bowel than in any other.

On the left or lower aspect of the root of the sigmoid mesocolon is oftentimes a peritoneal pouch, the **intersigmoid fossa**, in which the occurrence of at least two cases of strangulated *sigmoid hernia* has been reported. This fossa is *funnel-shaped*, and its *opening* looks downward and to the left and is generally over the bifurcation of the iliac vessels. It is *found* by turning the flexure to the right. The fossa is 1 to  $2\frac{1}{2}$  inches deep, is more constant in the infant than in the adult, and is caused by the sigmoid artery.

The **rectal or colon tube**, cannot be passed beyond the sigmoid loop under normal conditions, but the irrigation of the colon can be accomplished with the tube in this loop. In case of habitual constipation a doughy tumor may be present in the sigmoid colon. Such tumors, and those of other kinds in this part of the bowel, may press upon the branches of the lumbar plexus, such as the anterior crural or obturator, and cause neuralgia.

**Colotomy** may be performed in either lumbar region, especially in the left, to establish an artificial anus when there is obstruction below.

**Lumbar colotomy** (Amussat's operation) is preferably done on the right side for it is nearer the anus. (See Lumbar Region.) The *line* of the descending colon is approximately that of the outer border of the quadratus lumborum, *i. e.*, a vertical line one half inch behind the center of the iliac crest. The line of the ascending colon is a little more mesial. The *obliquely transverse incision* is placed, with its center in the above line, below the level of the kidney, as the latter intervenes between the colon and the parietes higher up. In the lumbar operation the colon is opened retroperitoneally along the attached area which, in the empty state, varies from four fifths to one inch in width, and in the distended condition may reach two or more inches (Braune). In thirty-six per cent. of cases the descending colon has a mesentery, and so cannot be readily reached extraperitoneally. On the retroperitoneal surface neither the appendices epiploicae nor the longitudinal

bands aid us in distinguishing the colon, for the latter are not visible and the former are not present.

In the new-born the *costo-iliac* space is very limited and entirely occupied by the kidney, so that, although the colon is then altogether outside of the kidney, colotomy is done in the inguinal region.

**Inguinal colotomy** (Littre's operation) is the one most often practiced in adults as well as in children. The *oblique incision* is parallel with and a short distance ( $1\frac{1}{2}$  inches) from the outer half of Poupart's ligament, and may be intermuscular. The opening is made in the sigmoid loop preferably at its upper end, for the danger of prolapse of its mucous membrane is thereby diminished. A transverse spur of mucous membrane, made opposite the lower end of the opening, prevents the contents passing into the lower segment of the gut. We easily distinguish the sigmoid loop from the coils of the small intestine, which often present themselves, by the bands, sacculi and appendages and by its position.

### The Liver.

The liver (Figs. 71, 74, 75 and 77) is the largest gland in the body and, on account of its bulk as well as its position, it is much exposed to injury. In size it averages 7 to 10 inches from right to left, 3 to 6 inches from before backward, and 6 to 7 inches from above downward, in the right lobe. It is larger in men than in women and, pathologically, it is subject to great variations in size and weight, especially to enlargement. At birth it is relatively much larger than in the adult, reaching below the costal margin and as far to the left as the spleen. Owing to its size and weight in the infant, a baby is not laid on its left side soon after feeding, on account of the pressure of the right lobe on the stomach. It is not until the sixth or eighth year of childhood that the anterior border gets level with the right costal margin.

Its weight is between 45 and 60 ounces, but varies according to its size and the amount of blood contained. As it contains nearly half a kilogram of blood it weighs much more during life than at post mortem. At birth it is one twentieth of the weight of the body, in the adult male one fortieth. Its volume is about 95 cubic inches.

The consistency of the liver is *firmer* than that of other glands, but it is *friable*. This fact, together with its size and fixity, explains why it is more often ruptured from contusion than any other abdominal viscous. Free *hemorrhage*, often fatal, results from such an injury because the hepatic veins are held open by the liver substance, to which their walls are adherent, and there are no valves in the portal and hepatic veins.

The liver is *moulded* to the surrounding organs which give it its *shape*, that of an ovoid bevelled off on its under part, especially at the left end. When examined in position we find three surfaces, a *posterior* resting against the upper part of the posterior abdominal wall, here formed by the diaphragm; an *upper* fitted into the vault of the diaphragm, and hence looking forward also in front; and an *inferior*

which rests upon the abdominal viscera as upon a pillow. The *left lobe*, large at birth, diminishes so much in size in early life that the falciform ligament, which represents the division between the right and left lobes and contains the round ligament in its free edge, is displaced to the right of the median line. Hence median abdominal incisions pass the umbilicus on the left to avoid incising these ligaments in regaining the median line above the umbilicus.

**Position.**—The liver lies in the right hypochondrium and the epigastrium, and extends into the left hypochondrium a distance varying from  $1\frac{1}{2}$  or 2 inches beyond the left margin of the sternum to the left mammary line. When enlarged it extends further to the left, under the left false ribs and in front of the stomach and the spleen, as in the child. The bulk of the liver and the entire right lobe is to the right of the median line.

Throughout its extent it occupies the vault of the diaphragm, hence its upper limit is on a level with the lower end of the mesosternum in the middle line, the middle of the fourth intercostal space in the right mammary line, the seventh rib at the right side and the upper end of the fifth space in the left mammary line. Behind it becomes superficial below the right lung, opposite the tenth and eleventh thoracic vertebrae and ribs, but its upper limit, covered by lung, is level with the ninth vertebra. It is overlapped above by the thin margin of the lung, below this by the costophrenic sinus. Over the latter area pleura and diaphragm intervene between the liver and the chest wall. Hence, a *penetrating wound* in the area between the upper extent of the liver and the lower limit of the lung<sup>1</sup> (see lung, p. 218), or the line of absolute liver dullness, may involve the pleura, right lung, diaphragm, peritoneum, and liver, penetrating four layers of pleura. Or, if the wound be a little lower, it may escape the lung and only involve the two layers of pleura of the costophrenic sinus, in addition to the diaphragm, etc. In front the xyphoid cartilage and the costal cartilages, from the sixth to the ninth inclusive, and on the right side the ribs, from the seventh to the eleventh inclusive, cover the convex surface of the liver, the diaphragm being interposed.

In percussing the chest from above downwards we find a region of relative liver dullness, where the liver is overlapped by lung. This dullness increases as we pass to the lower border of the lung, where we reach the line of absolute liver dullness. This is at the sternoxyphoid articulation in the median line, the sixth intercostal space in the right mammary line, the seventh rib in the axillary line, and the lower border of the ninth rib in the scapular line. The line of relative and absolute liver dullness is liable to variation with the changes in position of the diaphragm in respiration; in diseases affecting the extent and condition of the lung; in pleuritic effusions; in abdominal tumors, ascites, or distension; and in variations in position or size of the liver.

The lower limit of the normal adult liver corresponds to that of its

<sup>1</sup>In the fifth or sixth intercostal space in front, the sixth at the side, and the seventh, eighth or ninth behind.

*anterior border* in front. In the *median line* it is at a point midway between the sternoxiphoid articulation and the umbilicus; in the *mammary line* at, or half an inch below, the costal margin; on the *right side* it follows the tenth and eleventh ribs, without extending over the anterior end of the latter as a rule; and *behind* it reaches the level of the lower end of the eleventh thoracic vertebra. This would represent the *lower limit* of the *liver dullness* except behind, where it is continuous with the dullness of the lumbar region. If on the right side one can palpate the liver below the tenth and eleventh ribs in quiet breathing, the liver is enlarged or displaced downward. On the extreme right the lower limit of the liver may reach the level of the second lumbar spine. In the *subcostal angle* the liver is in contact with the anterior abdominal walls, and its *lower limit* is represented by a line drawn from the ninth right to the eighth left costal cartilage. Here one can *palpate* the lower or anterior margin of the liver when the abdominal walls are thin.

The liver is quite *movable* and its lower limit is therefore subject to variation from physiological and pathological causes. Thus owing to its intimate relations with the diaphragm it moves upward and backward in expiration, downward and forward in inspiration, so that with a deep inspiration its anterior border may descend below the costal margin in the right hypochondrium, even in the reclining position. In the *reclining position* the edge of the liver is half an inch above the costal margin on the right side in front; in the *erect position* it descends to half or quarter of an inch below this margin.

We have already noted the difference in children up to the sixth or eighth year. In women it is apt to reach a lower level, owing to the use of corsets, and in those who lace tightly it may be pushed down even to the iliac fossa. In such cases of "*corset liver*" the right lobe is marked by a deep constricting *furrow*, due to the pressure of the costal margin. In this furrow the transverse colon or loops of the small intestine may sometimes be found, giving rise to a tympanitic resonance with dullness above and below.

In *uniform enlargements* of the liver, from any cause, it is displaced downward, where we can diagnose the enlargement by percussion and palpation. Enlargements of the liver also cause a bulging of the right lower ribs and costal cartilages. When, however, the upper part of the right lobe is involved in abscess or hydatids, the enlargement and the area of dullness extend upward, raising the diaphragm and encroaching upon the right lung. In emphysema, pleurisy with effusion, and other conditions associated with distension of the right side of the thorax, the lower level of the liver is lowered. On the other hand, in phthisis, collapse or retraction of the lung, also when the liver is abnormally small and in conditions involving distension of the abdomen the lower level of the liver is raised, so that we may have tympanitic resonance over the lower margin of the ribs.

From the above we obtain the limits between which the liver is *accessible to operation*. In the upper part of this area the liver lies

deeply, covered by the lower margin of the lungs, etc. Above the lower limit of the pleura we must pass through the latter and the diaphragm to reach the liver. This is necessary when the trouble affects the upper part of the liver, and may be safely done by suturing the diaphragm into the thoracic opening and then penetrating the diaphragm. If we resect the tenth rib *in the right axillary line* we find cellular tissue and diaphragm but no pleura, but on going through the diaphragm we open the peritoneal cavity and meet the liver.

The liver is held in position by its attachment to the diaphragm, within the area embraced by the coronary ligament, by the latter ligament, and by the lateral and suspensory ligaments. The latter ligament is of little or no service in suspension. Although the liver is firm in position as compared with other intraperitoneal organs yet, as we have seen, it is also subject to variation in position. From the relaxation of its ligaments, especially in women after childbirth, a "dislocation" of the liver, or a "wandering liver" may result.

According to Hasse the liver is *stretched in inspiration* and *compressed in expiration*. Doubtless the movements of respiration stimulate its circulation, and probably on this account it is placed between the diaphragm and the abdominal walls. Thus a bon vivant or one of active habits suddenly confined to bed, by a broken limb, etc., becomes bilious from a congestion of the portal circulation, owing to the little stimulation it receives from the movements of respiration, which is now quiet.

**Relations.**—The diaphragm above separates the *upper surface* of the liver from the *pleural and pericardial cavities*. The latter corresponds to a flattened area on the upper surface of the left lobe. The close relations of the liver with the pleura, lungs and heart, explains how hydatid cyst or abscess may burst into the pleura or lung, or even into the pericardium. Thus it happens that pieces of liver, disintegrated it is true, may literally be coughed up. Similarly empyema has been known to penetrate the diaphragm and give rise to a sub-diaphragmatic or an hepatic abscess. The liver may also be damaged when the *right lower ribs* are fractured, owing to their close relations. The broken ends of the ribs have, in some cases, been driven into the liver through the diaphragm. If the smooth upper surface of the liver is roughened by inflammation its movements in respiration give rise to a friction sound similar to that in pleurisy.

The *posterior surface* of the liver *rests upon* the right suprarenal body, to the left of this it is grooved for the vena cava, and further to the left it lies upon the crura of the diaphragm, with the various vessels and nerves between or within them, and the oesophagus. In case of great enlargement of the liver these structures may suffer a certain degree of compression. The possibility must be admitted of a *rupture of the liver* without tearing the peritoneal coat. Such injuries are not often fatal. They may reach the surface of the organ behind, on the fairly extensive non-peritoneal surface. Here also a *wound* may occur or an *incision* be made into the liver without opening the peri-

toneal cavity but, owing to its position, only after passing through the pleural cavity.

The under surface of the *right lobe* is *in contact with* the upper half or two thirds of the right kidney and the suprarenal capsule, to the left of this with the duodenum (first and second parts), and in front of these with the colon. To the left of the neck of the gall-bladder lies the pyloric end of the stomach in relation with the quadrate lobe. The *lower surface* of the *left lobe* projects as the tuber omentale, which rests upon the lesser omentum, and in front of and to the left of this it is concave, where it covers the lesser curvature, cardia, and part of the anterior surface of the stomach, to an extent varying inversely with the fullness of that organ. It may even cover the fundus of an empty contracted stomach.

From these relations we see that an *abscess of the liver*, after inflammatory adhesion, *may open* inferiorly into the colon, duodenum, stomach or right kidney, and also that an abscess of or about the right kidney may extend to the liver. Abscesses of the liver are frequently *due to* an inflammation, like dysentery, of some part of the alimentary canal the blood from which is returned by the portal vein, through which the infection is carried. Such abscesses, like their cause, are especially frequent in hot climates and hence are called "*tropical abscess*." They may also follow surgical operations upon the same parts. The secondary or *metastatic abscesses of pyemia* are frequently found in the liver and, according to Bryant, more often after injuries to the head than after other injuries. Tillaux states that metastatic abscesses are superficial, other abscesses deeper.

We have already seen some of the positions in which hepatic abscesses may perforate : in addition there may be mentioned the peritoneal cavity and the surface of the body, after adhesion of the liver to the body walls. In the latter instance the abscess is preferably opened below the costal margin when it is accessible there.

*Hydatid cysts* occur more often in the liver than in all other viscera taken together. They may discharge themselves in the same manner as hepatic abscesses.

**Coverings and Structure.**—The liver is covered by *peritoneum* except (1) over the areas between the layers of peritoneum which constitute the ligaments by which it is held in position ; (2) along the transverse fissure, where the lesser omentum is attached and the vessels and ducts enter or emerge ; and (3) at the bottom of the fissure for the gall-bladder, where the latter intervenes between the liver and peritoneum. Hence, most operations, wounds or affections of the liver, which reach the surface, must involve the peritoneum.

Beneath the peritoneal coat, or in place of it where it is wanting, is a thin coat of *fibrous tissue*, which at the transverse fissure accompanies and loosely invests the vessels and ducts throughout the liver. This fibrous tissue, *Glisson's capsule*, forms a lattice-work throughout the liver, which is thereby divided up into minute lobules, 1–2 mm. in diameter. This fibrous lattice-work may become *swollen in cirrhosis*.

or in hepatitis. In the latter the swelling is the result of acute inflammation, and the liver is enlarged and tender. In cirrhosis the swelling is usually due to chronic alcoholic irritation which, if continued, results in hypertrophy of the fibrous tissue. This produces a large, hard liver, the first stage of cirrhosis. The swelling or hypertrophy, obstructing the flow of bile from the lobules, causes a certain degree of jaundice, from the absorption of the coloring matter, and dyspepsia is a constant symptom. The subsequent contraction of the new fibrous tissue renders the liver hard, fibrous and smaller than normal, and compresses the branches of the portal vein. This causes great congestion of the parts which feed the portal vein, *i. e.*, the stomach, intestines, pancreas and spleen. This results in varicose veins of these parts, from which serous exudations (*ascites*) and hemorrhages may occur, and aggravates the functional disturbance of the digestive tract. The surface of the liver becomes rough and irregular (*hobnailed liver*), owing to the contraction of the fibrous lattice-work which reaches the surface.

The liver may be *greatly and uniformly enlarged*, even so as to reach the umbilicus, in certain diseases of the heart and lungs where the flow of blood from the hepatic veins into the vena cava is impeded, owing to the congestion of the right heart. Fatty degeneration is another condition which may cause an enlargement of the liver, sometimes of enormous size.

**Vessels and Nerves.**—These, invested by Glisson's capsule, enter the liver at the transverse fissure, which they reach by ascending between the two layers of the small omentum near its right margin and in front of the foramen of Winslow.

The **hepatic artery** supplies largely the duct and vessel walls and the fibrous tissue of the liver. Brewer has called attention to the frequency of anomalies in the position and branching of this vessel, which, however, are seldom of surgical importance. The **portal vein** brings by far the greater part of the blood to the liver and practically all that which reaches the liver cells. The results of *obstruction of the portal vein* are seen in enlargement, congestion, varicosities, hemorrhage, serous exudation within (*diarrhoea*) and without (*ascites*), and impairment of the function of the viscera containing the sources of the vein.

In such cases the *anastomotic circulation of the portal system* comes into play, viz., certain of the superficial branches on the liver with the phrenic veins; the veins of the round ligament with the epigastric veins; the hemorrhoidal veins with branches of the internal iliac; the gastric with the oesophageal veins; and small branches on the pancreas and on the parts of the intestine destitute of a mesentery with the veins of the parietes and viscera (left kidney), with which they are in contact.

**Lymphatics.**—The superficial set on the posterior half of the liver passes to the mediastinal nodes; on the anterior half of the liver those on the right of the gall-bladder pass to the lumbar nodes; those on the left of the gall-bladder, to the oesophageal and mediastinal nodes; those about the gall-bladder and the fore part of the upper surface to

PLATE XXXVII.

FIG. 74.

Viscera of the upper part of the abdomen. The liver is lifted up, showing the gall-bladder and the upper part of the gall-ducts. (Testut.)

the nodes of the small omentum near the transverse fissure, where they join the deep set.

The **nerves** are from the *left vagus* and the *cæliac plexus* (sympathetic). The former filaments, fewer in number, pass from the lesser curvature of the stomach between the folds of the small omentum. The *pain over the right shoulder* in liver disease, such as hepatitis, etc., is a *reflex* in the *supraacromial nerve* due to the fact that it is a branch of the fourth cervical nerve, which also helps to form the phrenic nerve, filaments of which enter the liver from the diaphragm. This reflex pain is commonly on the right side for the right lobe is usually chiefly involved.

**Carcinoma** of the liver is a common condition, not as a primary but as a secondary or metastatic growth, usually from the stomach, intestines, uterus, or mammae. These growths are, as a rule, multiple and diffuse. When not diffuse a tumor of some size may be *removed*, for a considerable part of the liver may be removed without disturbance of function. Experimentally three fourths have been safely removed in animals. The part remaining hypertrophies and probably the liver may be regenerated. In such cases the escape of bile is not usual, nor is it necessarily fatal. *Hemorrhage* can be controlled by the cautery in case of the small vessels, the clamp or suture in larger vessels which, as we have seen, are held open by their connection with the tissues in which they lie.

**Varieties** are *not common* in the liver. The *left lobe* may be unusually small or large, or a portion of it may be connected with the rest by a pedicle of peritoneum containing only blood vessels and so an abdominal tumor may be simulated.

### The Gall-Bladder.

The *pear-shaped* gall-bladder (Figs. 71 and 74) is 3 to 4 inches *long* by  $1\frac{1}{2}$  inches *wide* at the fundus and will contain 1 to  $1\frac{1}{2}$  ounces. It may become greatly *enlarged* from the obstruction of the cystic duct and some forms of obstruction of the common duct, so as to contain a pint and more and extend even below the umbilicus. It is so *lodged* in the fossa of the liver that its larger end, or *fundus*, projects forward, downward and to the right, beyond the anterior margin of the liver, so as to *lie* behind the abdominal wall below the edge of the ninth costal cartilage and just lateral to the right rectus muscle. When *enlarged* it can be percussed and palpated external to the rectus muscle. Such a tumor moves with respiration for it is connected with the liver.

When normal the gall-bladder cannot be palpated. It may lie entirely under cover of the liver whose anterior border is usually notched (*incisura vesicalis*) over the fundus of the gall-bladder. Its narrow end or *neck* extends backward, upward, and to the left toward the transverse fissure, where curving first to the right and then to the left, it *opens* into the *cystic duct* which continues its spiral curve.

It is *held in position* by the attachment to the liver of its upper sur-

face by areolar tissue and of its under surface and fundus by peritoneum reflected from the liver. Occasionally the peritoneum completely surrounds the gall-bladder, forming a short *mesentery* which suspends it from the under surface of the liver. It can be readily stripped by blunt dissection from the under surface of the liver after its peritoneal attachment is divided.

The *upper surface* is in relation with the liver, the *under surface* is in contact with the hepatic flexure of the colon in front, and with the bend between the first and second portions of the duodenum and often-times with the pyloric end of the stomach behind, near the neck. These parts are found stained with bile after death, and into these parts gall-stones may pass from the gall-bladder after adhesion and ulceration. A fistulous tract from the gall-bladder may also open on the surface of the abdominal wall and allow the escape of gall-stones and bile.

Beneath the partial peritoneal covering the wall is made up of *fibrous tissue* with some *muscular fibers*, principally longitudinal, and it is lined with mucous membrane. The *viscid secretion* of the latter mingles with the bile, hence the bladder is more than a reservoir. Its secretion is often the principal content of the distended bladder (*hydrops of the gall-bladder*), as when the cystic duct is obstructed.

Gall-stones are frequently present in the gall-bladder, often without giving any sign of their presence during life and only discovered at autopsy. They are *formed* mainly of cholesterine and vary from a flax-seed to a hen's egg in size. The smaller ones may pass through the ducts into the intestine, the larger ones, if passed, enter the bowel through a fistulous opening. It is impossible to feel gall-stones through the abdominal wall, in fact even through the open abdomen one cannot say whether a full gall-bladder has a stone in it or not. Though often innocuous they may cause *inflammation* of the gall-bladder. If its contents are purulent we call the condition *empyema* of the gall-bladder.

The *opening* of the gall-bladder, done on account of empyema, distension, etc., is called **cholecystotomy**. **Cholecystectomy** is the removal of the gall-bladder, which is done on account of a tumor, gangrene, or inflammation with obliterated cystic duct, etc. When an obstruction in the common bile-duct cannot be removed we open the distended gall-bladder and connect it with the jejunum, duodenum or transverse colon (**cholecystenterostomy**), so that the bile has a new route to the bowel. Nature sometimes performs the same operation by ulceration after adhesion.

*Rupture* of the gall-bladder as well as of the bile-ducts may occur with or without *rupture* of the liver. This injury is more likely to occur when the liver is enlarged and the gall-bladder distended, and is not necessarily fatal if the bile is normal, for then it does not excite *septic peritonitis*, but only when suppurative processes have pre-existed in the gall-bladder.

The numerous **lymphatics** of the gall-bladder pass to one or two small nodes at the bend of its neck. In inflammatory conditions they may become so enlarged as to cause obstruction by pressure.

The cystic duct (Fig. 74) is a tube  $1\frac{1}{2}$  inches long (1 to 3 inches, Joessel) by one twelfth inch wide, which runs in the lesser omentum from right to left to connect the neck of the gall-bladder with the hepatic duct, which it joins at an acute angle to form the common bile-duct.

The spiral curve of the neck of the gall-bladder and of the adjoining part of the cystic duct corresponds to the oblique crescentic folds of its lining mucous membrane, which simulates a spiral valve. The effect of this arrangement is to make it almost impossible to pass a probe along this duct, unless it has previously been distended by the passage of a stone. As it is the smallest part of the biliary channel, small stones that pass it can usually quickly pass the common bile-duct. It is remarkable what large stones pass the cystic and common ducts. It may be greatly enlarged by the passage of a stone or in chronic cases of obstruction in the common duct. Bile only flows into the gall-bladder when its flow into the duodenum is stopped.

Obstruction of the cystic duct is not followed by jaundice, for the flow of bile into the intestine is not checked, and though the gall-bladder may be distended it is due to its own secretion.

The right and left bile-ducts usually join one another at an obtuse angle near the right end of the transverse fissure, shortly after their exit from the liver, to form the hepatic duct, 1 to 2 inches long and one fifth inch in diameter. The latter is directed downward and to the right in the right margin of the small omentum.

FIG. 75.

View of the abdominal viscera from behind, after removal of the spinal column and the whole of the posterior wall of the abdomen, the peritoneum being left. (After His' model.)

The common bile-duct averages about three inches in *length* and one fourth inch in width. Its *course* continues that of the hepatic duct, lying between the layers of the hepatoduodenal ligament (*i. e.*, the right margin of the small omentum), in front of the foramen of Winslow to the first portion of the duodenum, behind which it passes. Thence it runs behind and internal to the second portion of the duodenum, between it and the head of the pancreas. It is sometimes surrounded by the head of the pancreas. It passes obliquely through the wall of the duodenum for three fourths of an inch, *opening* into the latter at the end of a papilla on its postero-internal aspect, about  $3\frac{2}{5}$  inches from the pylorus, or  $1\frac{2}{5}$  inches below the crescentic fold in the lumen of the first bend of the duodenum (see Duodenum).

The pancreatic duct usually *joins* the common bile-duct in the duodenal wall and below their junction there is a slight *dilatation* beneath the mucous membrane, **the ampulla of Vater**.

The papilla contains the *narrowest part* of the common duct, hence stones are likely to be arrested just above it in the ampulla. The papilla lies on a free edge of one of the valvulae conniventes, but is covered by a mucous fold above it, so that it is often difficult to find unless we can express a drop of bile or unless we know just where to look for it, hence the value of the above measurements. The oblique course of the duct through the duodenal wall, and perhaps the valvular folds of its mucous membrane, described by Toldt, prevent the backward flow of the intestinal contents. In their course the bile-ducts *lie* in front of and directly upon the portal vein, and to the right of the hepatic artery. The lower end of the common duct lies upon the vena cava, hence caution is required in incising the walls of the ducts.

The common duct may be *exposed at its lower end* by opening the second portion of the duodenum in which it may be felt by the finger as a cord-like channel, along the postero-internal aspect. By slitting up the duct, as it lies in the walls of the gut, for half an inch from its opening, we can remove stones impacted in its lower end, as McBurney has shown. *Above this point* we can *expose the duct* by incising the peritoneum on the right of the duodenum, loosening the latter posteriorly and drawing it toward the median line. Still higher we can expose the duct by dissecting up the first portion of the duodenum from its posterior attachment and drawing it downward. We may sometimes force a stone along the duct, especially after crushing it within the duct (*choledolithotomy*), a poor practice, or we may incise the duct (*choledocotomy*), remove the stone, and then suture the duct or drain it.

All the *operations* on the gall-bladder and ducts are *performed in* the so-called *subhepatic space*, *bounded by* the liver above and the colon and transverse mesocolon below. The duodenum occupies the floor of this space, and the pyloric end of the stomach encroaches upon the median side. By pushing the liver up and retracting the transverse colon down, and perhaps pushing the stomach to the left, we get room for exploration and operation, though all the biliary passages lie at an uncomfortable depth. As the result of inflammatory adhesion the

# PLATE XXXVIII.

FIG. 76.

Outline of lower half of bony thorax, showing the position of the spleen. (Merkel.)

FIG. 77

Outline of the abdominal viscera from behind, showing their relation to one another, the lower ribs and the vertebrae. Kidneys in black, spleen in red, liver in yellow, duodenal loop and colon in blue. (Merkel.)

subhepatic space may be obliterated, which greatly increases the difficulties of operation.

When a stone becomes *impacted* in one of the ducts the muscle fibers, which are mostly circular in the duct, make a violent spasmody effort to dislodge it. This may be partly successful, the stone may pass on a little ways and again become impacted, and so on. Thus attacks of *hepatic or biliary colic* succeed one another until the stone is passed or becomes more firmly impacted. A stone impacted in the common duct may partly or wholly stop the flow of bile into the duodenum. In the latter case the ducts above the obstruction become distended, the stools become clay-colored and the patient jaundiced. The gall-bladder, curiously enough, is rarely distended but is usually contracted in such cases. Obstruction may also follow pressure from without, as from a tumor of the head of the pancreas or the stenosis of the duct due to inflammation of its mucosa.

**Varieties.**—The gall-bladder may be constricted transversely or longitudinally, or may even be absent, in which case the hepatic duct is usually dilated before opening into the intestine.

### The Spleen.

**Position.** (Figs. 71, 76 and 77.)—The spleen, the largest and most important of the *ductless glands*, lies in the dorsal part of the left hypochondriac and epigastric regions, between the concavity of the diaphragm behind and to the left, the fundus of the stomach in front and to the right, the left kidney and the splenic flexure of the colon internally and below. Its *long axis* corresponds with that of the tenth rib, and it extends between the eighth and eleventh ribs. The *upper or larger end* extends to within  $1\frac{1}{2}$ –2 inches of the median line, or within one inch of the vertebral column, and sometimes touches the latter. It is on a level with the tenth thoracic vertebra or the ninth thoracic spine. Its *lower end*, which lies further downward, outward and forward on a level with the first lumbar spine, about reaches the mid-axillary line, but normally does not extend beyond the left costoclavicular line (*i. e.*, from the left sternoclavicular joint to the tip of the left eleventh rib).

The spleen, therefore, lies under cover of the bony thorax and *cannot be palpated* when normal. Its *position is affected by respiration*, though not so much as that of the liver, for the diaphragm exercises less influence upon it. It sinks somewhat in inspiration, pleural effusions, and emphysema; it rises in expiration, and is pushed up by ascites and abdominal tumors. When much enlarged it displaces upward the heart and left lung, causing palpitation and shortness of breath.

The spleen is held in position by peritoneal folds containing fibrous tissue strands; the *phreno-splenic ligament* (*lig. suspensorium lienis*) from the left crus of the diaphragm, and the *phreno-colic ligament* (*sustentaculum lienis*). The latter, passing from the diaphragm, opposite the free ends of the tenth and eleventh ribs, to the splenic flexure of the

colon, forms a pocket for the spleen in the new-born and holds it up by supporting the colon on which it rests. If the latter ligament becomes relaxed the spleen is *displaced* downward and lies more vertically. Rarely the spleen is found low down in the abdomen or even in the pelvis. Such a "*wandering spleen*" is liable to atrophy from a torsion of the vessels in the lengthened pedicle, and it may cause so much pain from stretching of the vessels and nerves as to require removal.

The *gastrosplenic omentum* affords but little fixation to the spleen, more to the fundus of the empty stomach. When the stomach is empty this omentum lies transversely, while the full stomach separates the two layers to cover its distended fundus. Thus the full stomach comes in direct relation with the spleen.

As to size, the spleen varies more than any other organ. Its *normal average* in the adult is about 5 inches in length, 3 in width, and  $1\frac{1}{4}$  in thickness; also 170–195 gms. in *weight* in the cadaver, and about  $\frac{1}{6}$  more when filled with blood. It is relatively large in childhood and atrophies in old age. It is *enlarged* during digestion, in cases of congestion of the portal vein, in malarial poisoning, leukæmia, and infectious diseases. It may attain such size as to reach the pelvis and nearly fill the whole abdomen, so as to be mistaken for an ovarian or uterine tumor, but unlike tumors of the kidney it is not covered in front by intestines. Its weight may equal 20 lbs. or more. In the child the enlarged spleen, in its earlier stages, is said to encroach upon the thoracic cavity more than in the adult, owing to the firmer support of the phreno-colic ligament in the young. More rarely the spleen is enlarged on account of abscess, cysts (especially hydatids) and malignant tumors. In cases of enlargement its limits may be determined by palpation even better than by percussion. The normal *notching* of its *sharp anterior border* helps to identify the spleen when enlarged below the costal margin. There are not infrequently *supernumerary spleens* partly or entirely detached from the mother organ, and in the latter case situated usually in the *gastrosplenic* or *great omentum*, or in the *transverse mesocolon*. On the other hand the spleen may be congenitally wanting.

Owing to its soft *consistence* it is very *friable* and therefore liable to *rupture*. But this accident is not common with the normal spleen, owing to the protection afforded by its position and relations and the fact that it is swung up by and rests upon elastic peritoneal folds. When *enlarged* the spleen is *more readily ruptured*, often by quite insignificant violence without trace of injury externally, and even by muscular violence, of which several cases are recorded. The spleen may be lacerated in severe fractures of the left ninth, tenth or eleventh ribs, by the broken end of a rib driven through the diaphragm, or by the direct violence which produced the fracture. Owing to the extreme *vascularity* of the spleen its *rupture* is often fatal from hemorrhage. The recovery of cases of limited wounds and gunshot injuries of the spleen is attributed to the contraction of the muscle fibers of its cap-

sule, which narrows the opening and favors the arrest of hemorrhage by coagulation of the blood.

**Relations.** (Figs. 72, 74 and 75.)—The convex *dorsal* or *phrenic surface*, directed backward, upward and to the left, is *in contact with* the diaphragm. It is separated from the parietes at its lower end by the diaphragm, higher up by the diaphragm and the costophrenic sinus of the pleura and above by the diaphragm and the lower edge of the lung. These relationships explain the cases where wounds of the spleen are combined with those of the lung and pleura and the rare cases where abscess of the spleen has perforated through the diaphragm into the left pleural cavity. The concave *gastric surface*, directed forward and inward, is *in contact with* the fundus of the stomach when the latter is full, but not when it is empty and contracted. The tail of the pancreas reaches its lower end. The upper end and the upper half of the outer border of the left kidney is in contact with the *renal surface*, which looks inward and downward. At the *lower and outer end* of the spleen is a *triangular area* which rests upon the splenic flexure of the colon and the phrenocolic ligament.

These relations explain the difficulty in percussing the normal or slightly enlarged spleen. Its upper end, above the tenth rib, is overlapped by the lung and covered by the thick muscles of the back. Below the lung it rests against the kidney and colon so that its limit cannot be defined by percussion, especially if the colon is filled with faecal masses. The difficulty is still further increased if the stomach is filled with food. The *lower and outer end* is the *only part determinable by percussion*, and even here faecal masses in the colon may interfere. The area of splenic dullness may disappear in emphysema and pleuritic effusions; and it varies in respiration as well as with any change in position or size of the organ.

The spleen is entirely *covered with peritoneum* except about the hilum, a row of depressions on the gastric surface just in front of the inner border, where the vessels enter or emerge between the two layers of peritoneum forming the gastro-splenic omentum. The latter, with the contained vessels, forms the *pedicle* which requires to be carefully ligated in extirpation of the spleen (*splenectomy*).

Of the vessels the *tortuous artery* is very large for the size of the spleen and renders it a very vascular organ. It also sends branches to the pancreas and to the fundus of the stomach (*vasa brevia* in the gastro-splenic omentum). The *splenic vein* goes to form the portal vein and is double the size of the artery. It lies below the artery and is much straighter than it. The *lymphatics* collect in nodes at the hilum, from which vessels pass to the thoracic duct.

Although the spleen is rich in blood vessels it is poor as to *nerve supply* which comes from the solar plexus and the right pneumogastric.

**Extirpation of the spleen** (*splenectomy*) is indicated and has been done for wounds and ruptures, cysts and abscess, simple and malarial hypertrophies and "wandering spleen." For the latter condition, *splenopexis* has also been advised and performed by stitching the spleen in

place and forming a new peritoneal shelf for it. Splenectomy for leukæmic enlargement has been practiced but, owing to its uniform fatality, is not now considered justifiable. In splenectomy a *free incision* is made along the left costal border, or sometimes in the median line or in the left semilunar line. The most important and difficult feature is the securing and ligation of the pedicle, the gastrosplenic omentum, with the very large vessels contained. If too much traction is made there is danger of tearing these vessels, especially the splenic vein.

### The Pancreas.

The pancreas (Figs. 71, 72, 74 and 75) is a *retroperitoneal* organ and lies deeply in the epigastric and left hypochondriac regions, behind the stomach and lesser peritoneal sac and between the duodenum on the right and the spleen on the left. Hence it is not easily accessible for surgical or diagnostic purposes. It crosses the median line in front of the first and second lumbar vertebræ, from  $2\frac{1}{2}$  to 5 inches above the umbilicus. Although it has been ruptured, wounded or even herniated (in some very rare cases of diaphragmatic hernia), these conditions never affect the pancreas alone, but only in connection with similar injuries of other neighboring viscera. It may sometimes be *felt* on deep pressure in emaciated subjects when the stomach and colon are empty.

It may be reached by raising the omentum and transverse colon, dividing the lower layer of the transverse mesocolon and elevating the upper layer, which covers the pancreas; or by dividing the gastrocolic or gastrohepatic ligaments, and then the peritoneum at the back of the lesser peritoneal sac.

Although it has relations with many most important structures, many of these relations are of no surgical interest. The lower end of the common bile-duct lies in a groove, often a canal, in the head of the pancreas. Hence carcinoma or chronic inflammatory enlargement of the head of the pancreas may so press upon the duct as to partly or completely occlude it and cause persistent jaundice. This part of the pancreas has the vena cava, vena portæ, aorta, and superior mesenteric vessels, etc., behind it, so that removal of tumors here situated, unless encapsulated, is almost impracticable, although it has been done. The pancreas also lies in front of the left renal vein and the right renal vessels, and its tail is in front of the hilum and the middle or upper part of the left kidney. These relations are to be borne in mind in nephrectomy.

The pylorus of the full stomach lies in front of the neck of the pancreas. The splenic vein and artery lie in grooves, respectively behind and above its upper border. The tail of the pancreas touches the spleen at its lower end and at the dorsal and lower part of the gastric surface. In operations on the pylorus or the spleen it is important not to wound the pancreas or to include it in the ligature, for, according to Billroth, the secretion of the pancreas may perhaps interfere with the healing of the wound by dissolving the cicatrix and lead to an obstinate

fistula. Perforating ulcers of the rear wall of the stomach may result in adhesion of the latter to the pancreas or, rarely, in abscess of the pancreas. A biliary calculus lodged just beyond the ampulla of Vater, or in the papilla, obstructs the pancreatic duct, which usually joins the common bile-duct in the duodenal wall just above the ampulla. An accessory communicating duct, *the duct of Santorini*, in the head of the organ above the pancreatic duct, may open separately into the duodenum an inch or so above the papilla and afford an outlet for the pancreatic secretion in such cases.

*Cysts* occasionally occur in the pancreas, the result of obstruction of the duct or other causes. Such cysts appear in the epigastrium above the umbilicus, usually below the stomach, which is pushed up, and above the transverse colon. They require opening and drainage of the fluid, which may be under great pressure. Acute inflammation of the pancreas (*pancreatitis*) may involve hemorrhage, necrosis or abscess of the pancreas, fat necrosis or general peritonitis, and demands operation. Chronic pancreatitis may obstruct the common bile-duct by pressure and also calls for operative treatment.

### The Kidneys.

**Position.** (Figs. 71, 77 and 78.)—The kidneys lie *retroperitoneally* and are deeply placed, one on either side of the spine, so that they cannot be palpated when normal in size and position, except the lower end of the right kidney in some cases. They *approach the surface* most nearly below the twelfth rib and to the outer side of the erector spinae muscle. When palpable they may be *best felt* from in front just below the costal margin and external to the rectus muscle, while the other hand presses forward from behind below the last rib.

The vertical line perpendicular to the middle of Poupart's ligament, which marks off the regions of the abdomen, cuts the kidney longitudinally so that one third of it lies to the outer side and two thirds to the inner side. The infracostal plane, connecting the lowest points of the tenth costal cartilages, cuts the lower ends of the kidneys, though it is not infrequently above the lower end of the left kidney. Hence the kidneys are *found in the following regions*, epigastric, hypochondriac, umbilical, and lumbar, but mainly in the two former and little or none in the lumbar region, where they are often incorrectly thought of as being. In the female and the child they are, as a rule, slightly *lower*, often reaching the level of the iliac crest. In the male also they are not infrequently lower than normal. In most cases the *right kidney* is about half an inch *lower* than the left, especially at the upper end, but exceptions are common. With these modifications in mind we may say that the kidneys *correspond to* the last thoracic and the first two or three lumbar vertebræ. The left kidney extends from the level of the lower end of the eleventh thoracic spine to a little below the second lumbar spine.

The **position** of the kidney may be *indicated posteriorly* by a parallelogram whose upper and lower ends are drawn horizontally outwards

from the two latter points, about 4 or  $4\frac{1}{2}$  inches apart, while the sides are drawn vertically 1 inch and  $3\frac{3}{4}$  inches from the spine (Morris). The *outer border* therefore reaches a point  $3\frac{1}{2}$  to 4 inches from the lumbar spines. The *twelfth rib* crosses the position of the kidney in such a way that one third or more of the organ is above it, under cover of the thoracic wall. This rib is sometimes *resected* in operations upon the kidneys in order to gain more room, and with care it may be done without risk to the pleura. But in one case, with rudimentary twelfth rib, the eleventh rib was removed for the twelfth, the pleura opened and death resulted. The *eleventh rib* overlaps the upper pole of the left kidney and the tips of the transverse processes of the first and second lumbar vertebræ overlap the mesial border of both kidneys. The *lower end* of the right kidney is, on the average,  $1-1\frac{1}{2}$  inches above the iliac crest behind and the level of the umbilicus in front, hence the kidneys lie higher than often supposed.

*In front* the *upper ends* of the kidneys about correspond to the interchondral articulation of the sixth and seventh costal cartilages, and they extend downward from here 4 or  $4\frac{1}{2}$  inches, *i.e.*, to an inch or so above the umbilicus. The *shortest distance* between the two kidneys above is about  $2\frac{1}{2}$  inches. The *hilum* is about two inches from the median line and opposite the first lumbar spine. Owing to the oblique position of the kidneys, the axis sloping downwards and outwards, the *lower pole* of the organ, or the center of the lower end, is one half or one inch further from the median line than the upper pole, which is two inches from it. The *inner border* of the right kidney lies very close to the *vena cava*, that of the left kidney an inch or more from the *aorta*.

The slight *downward movement* (one half inch, Holden) of the kidneys *in inspiration* or their lower position in accumulations in the pleura are accounted for by the relation of the kidneys to the diaphragm and to the organs like the spleen and liver, which move with it. The kidneys also lie slightly lower (about one half inch) in the standing than in the reclining position.

**Posterior Relations.** (Fig. 78.)—The kidneys *lie upon* the diaphragm above and the quadratus lumborum, transversalis and outer border of the psoas below, the muscles being covered by their respective fasciæ. Intervening *between the quadratus muscle and the kidney* are the last thoracic, iliohypogastric and ilioinguinal nerves and the first lumbar vessels, all of which pass obliquely outward and downward and may be met with in exposing the kidneys from behind. The *last thoracic nerve* indicates the *lower end of the diaphragm*, above which it is not safe to incise. The area of contact with the diaphragm is larger on the left than on the right side, owing to the higher position of the left kidney. But on both sides it is of great importance, as the kidney is here in close relation to the pleura, whose lower limit extends nearly horizontally from the lower border of the twelfth thoracic vertebra, meeting the twelfth rib about  $3\frac{1}{2}$  inches from the median line and the eleventh rib about 2 inches further laterally. If a marked *hiatus diaphragmaticus* exists above the *lig. arcuatum ext.*

PLATE XXXIX.

FIG. 78.

Position of the kidney with reference to the posterior abdominal wall. The dotted red line represents the position of the left kidney. (Testut.)

between the vertebral and costal portions of the diaphragm, the kidney may come in contact with the subpleural tissue. The relationship of the kidney and pleura explains (1) the frequency of perforation of perinephritic abscesses into the pleura, especially on the left side, a serious complication, and (2) the danger of opening the pleura in operating upon the kidney, especially if the last rib should be rudimentary and the eleventh rib be mistaken for it, from failure to count the ribs. As a rule the incision may be safely carried just below the lower border of the twelfth rib, but it must be remembered that sometimes that part of the pleura which extends below the twelfth rib reaches beyond the lateral margin of the quadratus lumborum, under otherwise normal conditions. A thirteenth rib would contract the space available for the lumbar approach to the kidneys.

**The anterior relations** (Figs. 72, 74 and 75) of the two kidneys are different. In front of the right kidney is the liver (renal impression) in the upper half, the ascending colon in the lower half, and the second portion of the duodenum along the inner margin. The following viscera lie in front of the left kidney in the positions indicated, the stomach in the upper third, the splenic vessels and pancreas in the middle third, and the descending colon in the outer part of lower third; while along the upper half of the outer border lies the spleen. Abscess of or about the kidney may involve the other organs in contact, such as the liver, spleen, or pancreas; or perforate and open into the colon, duodenum, or stomach. The above relations are also important to remember in nephrectomy. In the case of tumors or other enlargements of the kidney the resonant colon is pushed forward in front of them, hence there is tympanitic resonance in front. Tumors of the kidney have but little movement with respiration and they are rounded and not notched like the anterior margin of the spleen. The position of the kidneys under the spleen or liver explains how enlargement or dislocation of these organs displace the kidneys downward.

**Relations of the Kidney to the Peritoneum.**—The above viscera in relation to the anterior surface of the kidney, with the exception of the liver and stomach, intervene between the kidney and the peritoneum, so that the latter covers only a limited area of the anterior renal surface. This area is somewhat greater in the right kidney than in the left. The peritoneum covering the left kidney is derived from that of both the lesser and greater peritoneal sacs. The peritoneal covering is readily stripped from the kidney. According to Lange, the distance between the lateral edge of the quadratus muscle, internally, and the point where the peritoneum, external to the kidney touches the parietes is considerable but is less on the left side by at least one centimeter. It is in this space that we expose the kidney by the lumbar incision. The peritoneum forms a complete covering, *mesonephron*, in the congenital variety of floating kidney. The position of the kidney behind the peritoneum allows us to reach and operate upon it by a lumbar incision without opening the peritoneum, and explains why rupture is not so serious as with the liver, spleen, and

intestines, as the extravasation is usually extraperitoneal. *Wounds* of the kidney from behind may readily occur without injury to the peritoneum. Although the kidney is quite well protected by thick muscles behind, its consistence allows it to be not uncommonly *ruptured* by external violence. As it lies at the angle of the bend when the back is bent far forward, it may be caught and squeezed between the lower ribs and the ilium, or ruptured by a heavy weight falling upon the bent back, while the kidneys are caught in the bend.

The fixation of the kidneys is due to the imbedding fat (tunica adiposa), derived from the subperitoneal connective tissue, and to the overlying parietal peritoneum, which is connected with the kidney and its "fatty capsule." The latter, usually scant at birth, increases about puberty and in adult life and is found most abundantly along the borders and posteriorly. When this fatty tissue is absorbed, owing to emaciation from any cause, the kidney loses its support and may become movable from slight causes; tight lacing, enlarged liver, accumulations above the diaphragm, external violence, traction of the ureter, colon or duodenum, and increased weight of the kidney. As the kidney is also supported by *intra-abdominal pressure*, the exciting cause of a movable kidney may be a relaxation of the abdominal walls, as the result of labor, removal of tumors, etc. Hence we can understand why movable kidney is so much *more common in women* than in men. It is also *more common on the right side* (90 to 95 per cent. of cases) than on the left, a fact probably due largely to the liver, pressed down upon it by tight lacing, hammering on the kidney with each inspiration. The excursion of a movable kidney is limited by the length of its vessels. These may become lengthened and usually allow it to slip down far enough behind the peritoneum to be palpable below the costal margin in front. In *floating kidney* the *mesonephron*, or peritoneal pedicle containing the unduly long blood vessels, allows a wider excursion, to the anterior abdominal wall, the iliac fossa or even to the pelvic cavity. The longer the pedicle the greater the danger of torsion of the pedicle and atrophy or gangrene of the kidney. Movable kidneys, when the symptoms demand it, may be fixed by suture to the edge of a lumbar incision.

It is through this *fatty capsule*, which, if excessive, protrudes hernia-like into the incision, that we work our way by blunt dissection in order to expose the kidney through the lumbar incision. The looseness of this tissue permits the ready enucleation of the kidney, except in cases where it becomes adherent to the kidney as the result of inflammation. If scanty, the fatty capsule often appears as a fascial membrane, which may be mistaken for peritoneum or transversalis fascia. Again it is in this tissue that *perinephritic abscesses* develop, from disease of the kidney or neighboring parts or from injury. The spread of such abscesses we can understand from the looseness of this tissue and its continuity with the subperitoneal connective tissue. As such abscesses are in contact with the diaphragm above, they are not unlikely to perforate this and break into the pleura. Curiously enough

they rarely perforate the peritoneum. For further accounts of their course see posterior relations of the kidney (p. 335) and abdominal walls, lumbar region (p. 281).

**Misplacements and varieties** of the kidneys. One, more often the left, less often both kidneys, may be congenitally *misplaced*. This misplacement is downward as a rule, so that the organ lies in the iliac fossa, on the pelvic brim or even in the pelvis. One kidney is sometimes much *smaller* than the other, or both may be fused together as a *single fused mass* (1 in 8,000 cases), with one or two pelves and ureters, or more often as a *horseshoe kidney* (1 in 1,600 cases) joined at their lower ends across the median line by kidney or connective tissue. When joined by connective tissue this is no bar to operation, even to removal of half of the kidney. Rarely there may be either one or three kidneys.

The **hilum** of the kidney looks forward, more or less inwards and slightly downwards. Its posterior lip is thick and nearer to the median line. Of the principal structures which enter or emerge from the sinus at this slit-like aperture, the vein is in front, the artery behind it and the pelvis of the ureter the most posterior and inferior. Hence the *pelvis* is *most accessible to exposure from behind*.

The **vessels** form the important element of the *pedicle* in nephrectomy and are to be *ligated* together or separately and apart from the ureter if possible. In this connection it is well to remember that the left artery and right vein are shorter than their fellows and the shortness of the right renal vein sometimes embarrasses the operator in a nephrectomy or other operation on the right kidney. The renal arteries, about the size of the brachial, divide into about four large branches before entering the hilum, and in over forty per cent. of cases they present *irregularities in number, place of entry, etc.* Frequently one or more *additional arteries* are given off from the aorta, or its neighboring branches, and pass to the hilum, the anterior surface or either end of the kidney, most often to the lower end (inferior renal artery).

The *veins* are less often, but not frequently, *irregular*. They may accompany the additional arteries at either end of the kidney, or a branch may be found entering the hilum, with a branch of the artery, *behind the pelvis*. There would be danger of wounding the latter vessels in opening the pelvis from behind, for exploration or the extraction of a calculus. The frequency of the above irregularities in the vessels should be borne in mind in a nephrectomy, for several cases are recorded where supernumerary renal vessels, not entering at the hilum, have given rise to serious, if not fatal, hemorrhage.

Owing to the deep position of the kidneys, they and their *vessels* are liable to be *pressed upon* in the supine position by the viscera as well as by tumors or the gravid uterus. Hence their secretory functions are probably influenced by changes in posture, so that the latter might be utilized in therapeutics. *Congestion* of the renal vessels may be due to other causes than direct pressure, *i. e.*, impeded circulation

through the lungs or heart, inflammation, etc. Long-continued congestion begets increase of the interstitial fibrous tissue, the contraction of which later on produces *cirrhotic or atrophied kidney*, just as similar conditions in the liver produce cirrhosis of the liver. Owing to the *anastomosis* between the small vessels of the surface of the kidney and the branches of the lumbar vessels, blood letting, cupping, or counter-irritation in the loins may relieve congestion of the kidney. The *lymphatics* (both superficial and deep) accompany the blood vessels and enter the lumbar nodes.

The **nerves** of the kidney come from the *renal plexus* which is derived from the solar and aortic plexuses and the lesser splanchnic nerves. The communication of the renal and the spermatic plexuses accounts for the radiation of the pain of a renal colic to the testicle, etc. The nausea and vomiting, and other symptoms of intestinal colic, or the rectal and vesical tenesmus, sometimes present in a renal colic, are accounted for by the relation of the nerves of the kidney with the ganglia supplying the intestines and bladder. On account of the association between the renal plexus and the upper lumbar nerves pain may radiate along the latter in renal colic; and, on the other hand, caries of the upper lumbar vertebrae may be mistaken for renal calculus, on account of the location of the pain.

The kidney is surrounded by a thin but strong **fibrous capsule**. In the healthy condition this capsule can be *peeled off* from the kidney, leaving its *surface smooth*, for the two are only connected by a delicate reticulum of fibrous tissue and minute vessels. In a cirrhotic kidney, and some other lesions of the kidney, this reticulum is thickened so that it is difficult to peel off the capsule, and the renal surface is left very rough when it is so removed. Hence these facts are made use of in autopsies as indicating a healthy or diseased kidney. In some cases of nephrectomy, when it is difficult to shell out the kidney from its fatty capsule, owing to previous inflammation, it may be easier to remove it from within its fibrous capsule.

**Operations** on the kidney. The kidney is incised (*nephrotomy*) along its outer border for exploration, evacuation of pus, or removal of a calculus (*nephrolithotomy*). The entire organ may be removed (*nephrectomy*) or it may be secured in its normal position by suturing (*nephorrhaphy*) when movable.

The kidney is *exposed* for these purposes by a vertical or, preferably, an obliquely transverse lumbar *incision* in the iliocostal space between the lower ribs and the iliac crest. To gain additional room the incision may be prolonged forward as far as the rectus muscle or enlarged by making a flap. In nephrectomy for a very large tumor, some prefer the transperitoneal method, incising as a rule in the corresponding semilunar line. In the latter operation the kidney should be reached from the outer side of the colon to avoid the colic vessels. For the details of the lumbar incision see lumbar region, posterior abdominal wall, page 282.

### The Ureters.

The ureters are about 12 inches *long* in the male and of the average *width* of a goose quill (one fifth of an inch), but show here and there spindle-shaped enlargements. They begin *above* in a funnel-shaped enlargement, the pelvis, which, passing out at the back of the hilum, where it may be reached and opened, narrows as it descends until it attains the cylindrical character of the ureter opposite the lower end of the kidney. A slight constriction is said to occur about two inches below the kidney (Bruce Clark).

The *lumen* is *narrowest* at its lower opening and in its passage through the bladder wall, hence calculi are likely to be arrested here, where they can be readily felt through the vagina in the female. In cases of gradual dilatation, the ureters are capable of great *distension*, to the size of the thumb or even that of the small intestine. This is not due to a backward flow from the bladder, but to an obstruction in the lower urinary passages, causing distension and perhaps frequent contraction of the bladder, thus preventing the emptying of the ureter, for the ureters cannot be emptied when the walls of the bladder contract or its cavity is too distended. The *oblique passage* of the ureter through the bladder walls downwards and inwards for  $\frac{1}{2}$  to  $\frac{3}{4}$  inch *acts as a valve*, preventing reflux into the ureter, so that the fuller the bladder the more tightly is the ureter closed.

**Course.**—The ureters lie about three inches apart at their commencement and, converging as they descend in the umbilical (not the lumbar) region, they are about two inches apart as they cross the pelvic brim, near the sacroiliac joint, to enter the pelvis. They then follow the curve of the posterior pelvic wall about parallel with the sides of the sacrum. *In the male* they lie in the parietal attachment of the posterior false ligament of the bladder, in which they run forward and inward to reach the bladder  $1\frac{1}{2}$  inches apart and  $1\frac{1}{2}$  inches behind the prostate. *In the female* they lie in the base or root of the broad ligament three fifths of an inch external to the cervix uteri. Here they are crossed *in front* by the uterine arteries and pass through the uterine plexus of veins. They then cross obliquely the upper one third of the vagina, inclining forwards from the lateral vaginal wall to the vesico-vaginal interspace, and *pierce the bladder* opposite the middle of the front wall of the vagina. Hence in the female, a stone impacted in the lower half of the pelvic portion of the ureter may be *palpated* through the vagina and an extensive carcinoma of the cervix or upper end of the vagina may involve and obstruct the ureters. Their *course and relations* in the female pelvis are of vital *importance in operations* on the female pelvic organs, and many cases are recorded where the ureter has been *injured in operations* on these organs. As a result of these injuries several methods have been successfully employed of uniting the divided ends of the ureters or reimplanting them into the bladder or intestines, when divided low down.

The *relations* of the ureters are of importance for the purpose of finding or avoiding them as occasion requires. They cross obliquely

the psoas muscles and the genitocrural nerves, being connected loosely with the muscle but firmly with the external surface of the peritoneum. From the latter circumstance they can be *readily found* for, if the peritoneum is stripped up from the psoas, the ureters remain attached to the peritoneum  $\frac{1}{2}$  to 1 inch from the attachment of the latter to the vertebræ on the left side and a little more on the right side, where the ureter is displaced outward by the vena cava. Psoas abscess has been known to discharge through the ureter. On section between the second and third lumbar vertebræ the right ureter is 4 cm. from the parietal peritoneum external to the outer border of the kidney, the left is 6 cm. distant.

In their course *in the abdomen* the ureters are *crossed anteriorly* by the spermatic (or ovarian) and colic vessels. The vena cava is almost in contact with the right ureter on its mesial aspect, while the left is separated from the aorta by one inch above and half an inch below, opposite the aortic bifurcation. On the right side the ureter is in near relation to the appendix, and when the latter points inward and is adherent posteriorly the two may be in contact, though the lower ileum often intervenes. The possibility of injuring the ureter should be remembered in operations on the appendix. *Near the pelvic brim* it crosses the common iliac artery close to its bifurcation, or the beginning of the external iliac (more often on the right side), and lies behind the sigmoid loop on the left side and the lower end of the ileum on the right. These relations are important in ligation of the iliac arteries.

*In the pelvis* the left ureter is lateral to the sigmoid mesocolon. *At the bladder* the ureter lies below the obliterated hypogastric artery and, in the male, is crossed superiorly and internally by the vas deferens, which thus comes to lie between it and the bladder. The free end of the seminal vesicle overlaps it from below. The inner openings in the bladder are about an inch from one another and from the vesical outlet.

**Varieties and Malformations.**—There may be only a *single ureter* from a fused kidney, or *two or even three ureters* may arise from one kidney, from the late union, or non-union, of the middle pelvis which form the common pelvis. *Two malformations* may exist as the *cause of hydronephrosis*: (1) a kind of congenital valve at the commencement of the ureter and (2) an origin of the ureter above the lower end of the pelvis, so that the latter fills before being emptied and, when full, may press upon and close the valve-like opening of the ureter. In the latter cases the ureter appears to come from the upper or middle instead of the lower of the two or three middle pelvis that make up the common pelvis.

The flow of urine through the ureters is due to the *peristaltic contraction* of their muscular coats, and may be aided by gravity in the erect position. It occurs at *regular intervals*, sometimes every three fourths of a minute or so, sometimes, as I have seen, twice in four or five seconds and then, after an interval of sixteen to twenty seconds, twice again in four or five seconds.

PLATE XL.

FIG. 79.

Pelvic portion of the ureters, formation of the spermatic cord, rectovesical pouch, pelvic vessels, etc., in the male, seen from in front and above, the bladder being pulled forward. (Testut.)

The abdominal portion of the ureters (*i. e.*, above the pelvic brim) may be exposed by an *incision* used to expose the kidney, passing obliquely from near the costovertebral angle toward the anterior superior iliac spine and then curving toward the umbilicus; or by an *incision* like that for the common iliac artery, carried further upward. The walls of the ureter are about one twenty-fifth of an inch thick, composed mainly of muscular and fibrous tissue.

The *passage of a renal calculus* through the ureter is accomplished in much the same way as that described in the passage of biliary calculi and with a similar intense, intermittent pain, known as *renal colic*. The ureters have been *ruptured* by external violence. The resulting *extravasation* of urine is large, retroperitoneal and liable to suppuration, producing a lumbar, iliac or pelvic abscess.

### The Suprarenal Bodies or Adrenals. (Figs. 72 and 74.)

These are two *ductless glands*, one of which *rests on* the upper end and the adjoining parts of the anterior surface and inner border of each kidney. They are *separated from the kidney* by the perinephritic tunica adiposa, so that changes in position of the kidney do not affect the suprarenals. They are larger at birth than in the adult, they atrophy in advanced life, and are degenerated in connection with Addison's disease. They *rest upon the diaphragm* opposite the eleventh and twelfth ribs, and perhaps the tenth interspace, or opposite the adjoining portions of the eleventh and twelfth thoracic vertebræ. An interval of 2 to  $2\frac{1}{2}$  inches separates them from one another.

The left is *crescentic*, flattened from before backward, and extends lower down than the right along the inner border of its kidney, even to the hilum. In front lies the stomach, separated by the lesser peritoneal sac, and its lower cornu is crossed by the pancreas and the splenic vessels. Externally it is in contact with the upper end of the spleen. The right suprarenal is more *triangular*, laterally compressed and vertically elongated, but reaches no higher than the left, owing to the lower position of the right kidney. It is *related in front* to both the inferior and posterior surfaces of the right lobe of the liver (*impressio suprarenalis*); *internally* to the vena cava, which slightly overlaps it, and its *inferior angle* is crossed by the first bend of the duodenum. It lies behind the foramen of Winslow. The left suprarenal is covered with peritoneum above, the right below.

The *nerve supply* of the suprarenals is remarkably abundant, derived mainly from the solar and renal plexuses, with some branches from the phrenic and vagus nerves. The suprarenals are of little or no surgical importance as yet and may be disregarded in operations on the kidneys, except that the blood supply of the two is more or less connected, especially on the left side. The extract of these bodies is a remarkably strong astringent and has also been used therapeutically in Addison's disease, etc.

### Blood Vessels of the Abdomen.

The following is in addition to the mention made under the several organs and the parieties.

The **abdominal aorta** varies in its distance from the ventral surface in different individuals, but in general it *approaches nearer the surface* as it nears its bifurcation. Hence the *most favorable point for compression* of the aorta is just above the umbilicus, for it bifurcates just below and to the left of this point. But even here it cannot be readily felt or satisfactorily compressed unless the bowels are quite empty.

**Aneurism** is most likely to occur at or near the cœliac axis which is a weak spot, often giving way in injections of the cadaver, for here several large branches are given off and cause a sudden deviation in the course of the circulation. Such an aneurism gives rise to a *pulsating tumor* in the epigastric or umbilical region, but a tumor of the organs in front of the aorta (pylorus, pancreas, colon) may also receive a pulsation (not expansile) from the aorta. *Pressure of the aneurism* on the diaphragm, œsophagus, and stomach may cause dyspnoea, dysphagia and vomiting; on the vena cava oedema of the legs; on the renal veins, albuminuria; on the lumbar nerves, pain in the back, buttocks, or thigh; on the sympathetic plexuses, indigestion, visceral pains, reflex pains in the lumbar nerves, etc., etc.

Many of the *branches* of the abdominal aorta are of *large size*, the cœliae axis and superior mesenteric are of the size of the common carotid; the hepatic, splenic, and renals equal the brachial in size.

The number of minute *extraperitoneal anastomoses* between the branches of the parietal vessels (lower intercostal, phrenic, lumbar, iliolumbar, epigastric, and circumflex iliac) and branches of vessels which supply viscera not entirely covered by peritoneum (liver, kidney, adrenals, duodenum, pancreas, ascending and descending colon) are of great *importance in case of obstruction* to the arterial supply of the viscera. The corresponding *venous anastomoses* are of equal or greater importance in case of obstruction of either the vena cava or the portal vein. A *parumbilical vein* may also directly connect the portal vein with the epigastric, and thus with the external iliac veins, and be of much service in relieving obstruction of the portal circulation, as in cirrhosis. The above anastomoses explain the effect of surface blood-letting and counter-irritation in inflammation or congestion of the partly extraperitoneal viscera.

The *cœliac axis*, with a semilunar ganglion on either side, arises opposite the top of the first lumbar vertebra, about four inches above the umbilicus. The *renal artery* arises opposite the lower end of the same vertebra (that of the right side somewhat lower), the *inferior mesenteric* about two inches above the aortic bifurcation, or  $1\frac{1}{2}$  inches above the umbilicus. The *left renal vein*, crossing in front of the aorta, to reach the vena cava, is an exception to the *rule* that below the diaphragm the large veins pass behind the large arteries, while above the diaphragm they pass in front.

### Lymph Nodes of the Abdomen.

Besides the lymphatic nodes already noticed, in connection with the organs, there is a central series of *retroperitoneal lymph nodes* arranged in *two groups*. (1) The *lumbar nodes*, twenty to thirty in number, lie on the sides and in front of, or even between, the aorta and vena cava. Great *enlargement* of these nodes may cause *œdema* from pressure on the vena cava. They receive the lymphatics from the external iliac nodes, the pelvis, kidneys, adrenals and the sigmoid flexure. (2) The *cœliac nodes*, sixteen to twenty in number, lie above the pancreas, near the cœliac axis, and receive lymphatics from the stomach, spleen, pancreas, part of the liver and the mesenteric nodes.

### Nerve Supply of the Abdominal Viscera.

This is derived from a series of *plexuses* formed by the *sympathetic system* with some branches from the vagus and phrenic nerves. The two *great splanchnic nerves*, descending from the thorax, end in the two large *semilunar ganglia*, one on either side of the *cœliac axis*. These are united together, and with many small surrounding ganglia, by a network of fibrils to form the *solar or cœliac plexus*, which also receives twigs from the vagus and phrenic nerves. From this central plexus *branch plexuses* are derived which accompany the visceral branches of the aorta, except the inferior mesenteric, to the organs which they supply. The *renal plexus* also receives the lower splanchnic nerves. Mesial branches of the lateral sympathetic cords form the *aortic plexus* in front of the aorta below the inferior mesenteric artery, along which a branch, the *inferior mesenteric plexus*, passes to the viscera supplied by the artery.

These plexuses, and the nerves which go to form them, communicate with the thoracic and lumbar spinal nerves and thus account for many *reflexes*, *i. e.*, the reflex pains and muscular contractions in the course of the spinal nerves in case of peritonitis, etc. (see p. 251). The "sympathetic" or *reflex pain between the shoulders*, or about the angles of the scapulae, in some diseases of the stomach and liver, are probably due to a reflex in the fourth, fifth and sixth thoracic nerves, which supply these parts and communicate with the great splanchnic nerves which, through the solar plexus, go to supply the liver and stomach. Reflex pain in the tip of the shoulder has already been referred to (see liver, p. 325).

From the extent of these abdominal nerve centers, especially the solar plexus, we can understand what *profound effects*, collapse, vomiting and even death may attend an injury to them, or the viscera most closely associated with them. Hence the danger of a blow over the pit of the stomach, *i. e.*, over the solar plexus, which may even cause death without marks of external injury, and always causes shock out of all proportion to the extent of the injury. Hence also an injury to those viscera which are more remotely connected with the nerve centers, such as the descending colon which is supplied by the

inferior mesenteric plexus, only indirectly connected with the solar plexus, or even the ascending colon supplied by a part of the superior mesenteric plexus most remote from the centers, is accompanied by less serious symptoms. It is noteworthy that the nearer the lesion is to the stomach, other things being equal, the more profound are the nervous phenomena produced. *Distant pain* in disease of the abdominal viscera is not necessarily reflex but *may be due to pressure*. Thus pain in the knee may be due to the pressure of the sigmoid flexure, distended with faeces or affected with cancer, upon the obturator nerve.

## CHAPTER V.

### PELVIS AND PERINEUM.

#### THE PELVIS.

We have already studied, in a preceding section, the upper part or false pelvis which supports some organs and attaches many muscles of the abdomen. It remains to study the true pelvis and its viscera. The **external or superficial boundaries** of this region are not well marked, for it is covered by the parts of other regions, *i. e.*, the buttocks behind, the hips at the side and the perineum below. Hence there are but **few bony or other landmarks**. Some of these we have considered under the landmarks of the abdomen (see pp. 237-8).

From the pubic spine, mesially, to the symphysis we can make out the *front of the pelvic brim*, formed by the pubic crests, and below this the bodies of the two pubic bones, separated by the symphysis pubis. This part is covered in the female by a thick pad of subcutaneous fat, the **mons veneris**, which somewhat obscures the bony outlines. The mons veneris is separated from the abdomen above by a transverse furrow which meets the inguinal furrows about their center.

Still further down in the median line we can feel the **subpubic angle** on deep pressure behind the scrotum in the male, in the vestibule in the female. Leading from this angle to the ischial tuberosities we can trace the combined **rami of the pubis and ischium** on each side, which bound the perineum laterally and lie nearly in the **genito-crural furrows**. The latter are the furrows between the inner aspect of the thighs and the perineum and are continuous behind with the *gluteal folds*. It is near the inner end of the latter that the **ischial tuberosities** can be readily felt. In the sitting posture these tuberosities are only separated from the skin by the subcutaneous fat and a **bursa**. This bursa is *liable to inflammation* in those who sit a great deal, like coachmen, weavers, etc. Hence the construction of many so-called anatomical bicycle-saddles, for it is on the tuberosities that we rest in sitting. In the standing posture the tuberosities are overlapped by the lower borders of the *gluteus maximus* muscles. The ischial tuberosities form one end of *Nelaton's line* (see p. 427), and the line connecting them divides the perineum proper in front from the *ischiorectal fossa* behind.

In the *median line behind* we can feel the **spinous process** of the fifth lumbar vertebra, often indicated by a little furrow, and below this those of the sacral vertebrae, of which the third is the most prominent.

Following down in the median line, in the deep fold between the buttocks, we can feel the **tip of the coccyx**, behind which (especially in women) there is often a more or less marked dimple or depression of the skin (*foveola*). *Through the vagina or rectum* can be *felt* posteriorly the front of the coccyx and sacrum, laterally the spines, the inner aspect of the tuberosities and the bodies of the ischia and the great sacrosciatic foramina, and anteriorly the back of the pubic bones and symphysis and the obturator foramina. With a long finger or half hand, when the patient is anaesthetized, the **sacral promontory** can be felt above and behind, but if this can be felt in an ordinary examination by a finger of ordinary length the pelvis is considered abnormal. The promontory can also be felt on deep pressure through a thin lax abdomen, about on a level with the anterior superior iliac spines.

**The Bony Pelvis.**—Although in the bony state the outlet or *brim* of the pelvis is *heart-shaped* with the base behind, in the natural state the psoas and other muscles make it *triangular* with the base in front. The *outlet* of the pelvis is composed of *three bony points* separated by *three notches*. The two symmetrically placed posterior notches (sacrosciatic) are bridged across by the strong *sacrosciatic ligaments* which thus bound the pelvic outlet and make it lozenge-shaped. The *tuberosities of the ischium* may be quite close together in the male. I have seen this condition so marked as to embarrass one in lateral lithotomy. In the natural position of the pelvis the tuberosity lies behind and below the acetabulum, and only a trifle further behind it than the anterior superior iliac spine is in front of it. Also the *ischial spine* lies  $\frac{2}{3}$  of an inch above the upper border of the symphysis.

The **coccyx** may be *fractured* or *dislocated* as a result of falls or blows or during parturition, especially in those women in whom the coccyx is much incurved as the result of sedentary habits or horseback riding. The displacement of the fracture or dislocation may be readily made out by rectal examination, or by a finger in the rectum and the thumb on the surface. The *joint* between the coccyx and the sacrum may also be *diseased*. All these conditions are very painful, owing to the frequent movement at the seat of injury, due to the muscles attached to the coccyx (*gluteus maximus, coccygeus, levator and sphincter ani*). The injured bone may project into the rectum and be moved in defecation mechanically as well as by the sphincter and levator ani muscles. The sacro-coccygeal joint and the parts about the bone are supplied by the posterior divisions of the coccygeal and the second to the fifth sacral nerves and the anterior divisions of the fifth sacral and the coccygeal nerves, which may be the seat of a painful neuralgia (*coccydynia*). *Removal* of the coccyx may be called for on account of injury, joint disease or neuralgia.

**Sacro-coccygeal Tumors.**—These are *usually congenital*, and I have seen them attain such a size that the possessor, a man, wore skirts to conceal the enormous mass. Some, springing from between the coccyx and the rectum, contain epithelial cysts and even fragments of tissue, *i. e.*, cartilages, bone, muscle, nerve, skin, mucous membrane. They

are supposed to arise from the embryonic neureneric passage, or post-anal gut, though they were formerly thought to originate from Luschka's gland. These tumors are thyroid-dermoids. Dermoids also occur over the back of the sacrum and coccyx, where they may be confounded with spina bifida. Some take such a shape as to form "human tails." Attached human foetuses are often joined together at this part of the column, and here too third limbs (tripodesia) and parasitic foetuses are found attached.

**Sacro-iliac Joint.**—Normally there is no movement in this joint except, as Farabeuf has shown, a slight rotation on a transverse axis. Thus when the thighs are flexed onto the abdomen the conjugate diameter is shortened by the rotation upward of the innominate bones, the symphysis approaching the promontory. The reverse occurs on hyperextension of the thighs, which may therefore be made use of in obstetrics to slightly increase the conjugate diameter of the brim. In general the joint serves merely to break shocks, but some movement is said to occur when the ligaments are softened by disease.

The joint may become diseased as the result of injury, by an extension from spinal caries, etc., or spontaneously. In the two latter instances it is usually tubercular. In disease of this joint much pain is felt in standing or sitting, as in these positions the weight of the body is transmitted through it. This pain, besides being local, may also be of a peripheral reflex character over the sacral region (upper sacral nerves), in the buttocks (gluteal nerve), or even at times in the thigh and calf (lumbosacral cord). The above-named nerves supply the joint, which sometimes gets a small twig from the obturator nerve which, with the lumbosacral cord, passes over the front of the joint. The obturator nerve accounts for referred pain in the knee or hip joints.

If abscess forms it usually comes forward into the pelvis, as the anterior ligaments are much the thinner and weaker. Such an abscess may enter the iliopsoas sheath, perforate the rectum, or follow the lumbosacral cord and sciatic nerve to the back of the thigh, or the obturator nerve to the inner aspect of the thigh. More rarely the abscess may pass backward and point behind the joint. In examining the joint from behind, it is useful to know that the posterior superior iliac spine corresponds to its center.

In spite of the comparative weakness of the anterior sacro-iliac ligaments, above mentioned, dislocation never occurs except in fracture of the pelvis, or the rare luxation of the sacrum anteriorly. This fact is due to the very strong posterior sacro-iliac ligaments, which sling the sacrum from the ilium, and not to the wedge shape of the sacrum for, in the natural position of the pelvis, the base of the wedge looks downward and forward, i. e., in the direction in which the weight of the body would naturally tend to displace it. The wedge shape would prevent its being dislocated backward, but there is no tendency to this displacement. At the same time, owing to the irregularities of the bony surfaces and the slight projecting lips of the ilia in front and below, the sacrum is more or less wedged in between the ilia like the

keystone of an arch, to the pillars of which, the ilia, it transmits the weight.

The *innominate bones* can be *separated* at the *symphysis*, in *symphysiotomy*, but a very little distance without first straining the front of the sacro-iliac joint, then tearing the anterior ligaments and the cartilages connecting the bony surfaces. In addition to the tearing of the anterior ligaments the *periosteum* is usually *stripped up* for some distance on the ilium in front of the joint. As the axis of this separation or opening of the joint is at the back of the joint and passes obliquely downward and inward, the strong posterior sacro-iliac ligaments avoid injury and the pubic bones on being separated pass downward as well as outward.

The *symphysis pubis* is nearly 2 inches in *height*, and its *thickness* may reach nearly 1 inch. In *symphysiotomy*, proposed by Sigault in 1768 as a substitute for Caesarean section to enlarge the pelvic dimensions in labor in cases of contracted pelvis, a separation at the *symphysis* of  $2\frac{1}{2}$  inches increases the conjugate diameter by only half an inch. But, as the convexity of the child's head may project into the interval between the separated pubic bones, another half inch or so may be gained for the passage of the head. In addition to the laceration of the sacro-iliac joints resulting from the separation at the *symphysis*, to which we have just referred, the attachments of the pelvic viscera may be damaged. A slight separation of the pubic bones due to swelling of the fibrocartilage has been shown to occur toward the end of gestation, but during parturition the decussating tendinous fibers of the abdominal muscles, which cross in front of the joint, would tend to brace the bones more tightly together.

*Separation at the symphysis* without fracture of the bones has occurred from severe external violence, and Malgaigne has reported three cases where the violence was muscular merely, due to excessive action of the adductors of both sides.

**The Mechanism of the Pelvis.**—The *weight of the body is transmitted* from the sacrum through the pelvis *along two arches*, one for the standing, the other for the sitting posture. The *arch for the standing posture* consists of the sacrum, the sacro-iliac joints, the acetabula, and the thick ridges of bone along the ilio-pectineal line between the two latter points. For the *sitting posture the arch* is much the same, except that the ischial tuberosities are substituted for the acetabula. These *two arches* have been called the *femorosacral* and the *ischiosacral* respectively. The bone in the line of these two arches is much thicker than elsewhere in the pelvis. The sacrum occupies the position of the keystone for both arches (see above, p. 347).

To strengthen each arch its ends are joined by a *counter arch*, which completes a ring and serves as a tie to keep the sides of the arch from separating or collapsing. The counter arch or tie of the femorosacral arch is formed by the bodies and horizontal rami of the pubes, that of the ischiofemoral arch by the combined rami of the pubes and ischia. Thus the *ties* of both arches *meet at the symphysis*, to which is conveyed

a portion of the weight or strain. Hence the strain felt at the symphysis when increased weight is to be borne, as in pregnancy, abdominal tumors, etc., and hence the inability to stand or sit when the symphysis is diseased or weakened by injury or an unhealed symphysiotomy.

**Pelvic deformities** are also explained, according to the mechanism of the pelvis, by the weight acting on bones that have not become properly ossified in parts, owing to *rickets*, or on bones uniformly softened by the much rarer condition, *osteomalacia*. When the rickety child walks but little and sits most of the time, as they frequently do, the weight of the body thrusts the sacral promontory forward and downward, thus diminishing the conjugate diameter of the brim. The *counter pressure* comes from the ischial tuberosities and is most felt in the counter arch, which is narrowed and pushed forward at the symphysis, while the tuberosities may approach one another and narrow the transverse diameter of the outlet. If the rickety child is more on its feet, lateral counter pressure is exercised at the acetabula, and is felt mostly at the weakest part of the pelvis, *i. e.*, the counter arch. Thus while the acetabula approach one another more or less, the most marked change is a beak-like projection of the symphysis, the pubic rami sometimes running parallel with one another and close together, showing a collapse of the counter arch.

In the softer condition due to *osteomalacia*, which occurs only in adult life, these changes due to lateral pressure are most marked.

**Fractures of the Pelvis.**—Though the sacro-iliac joints and the symphysis might be thought to be weak points of the pelvis, their connecting ligaments are so strong that they rarely give way primarily; the bones yield first. As has been just said the *counter arch* is the *weakest point*, and it is *here that fracture commonly occurs* from the most varied forms of violence. Fractures of the pelvic arch usually occur as the result of violent pressure on the surface or of falls from a height. Thus, if the force be applied in the antero-posterior direction, the weak counter arch yields to direct or indirect violence on one or, possibly, both sides of the symphysis through the pubes or the rami. The force continuing tends to separate the two hip bones and to cause a diastasis and finally a dislocation of the sacro-iliac joints, as in symphysiotomy. Again, if the force be applied transversely, the pelvis tends to become flattened laterally, but the weaker counter arch is more bent and eventually gives way and is fractured by indirect violence. Should the force continue, the two hip bones are pressed toward one another and the strain on the sacro-iliac joint falls upon its posterior part. Here the ligaments are so strong that, instead of their rupture, portions of bone to which they are attached, especially the sacrum, are usually torn away. In falls on the feet or ischial tuberosities, it is again the weaker or counter arch which is usually fractured. In falls from a height or other severe injuries, the head of the femur may be driven through the acetabulum, but this is rare.

A separation of the hip bone into its three constituent parts cannot occur after about the eighteenth year, at which time the three parts are firmly united by the ossification of the Y-shaped cartilage. Before this occurs *abscess* within the capsule of the hip joint may make its way into the pelvis through the cartilage, but this is not as common an occurrence as one would expect. Localized direct violence of sufficient force may fracture any part of the pelvis.

Apart from the fact that the violence producing fractures of the pelvis is usually severe and entails shock and often other remote injuries, such fractures are serious on account of and in proportion to the *injury to the pelvic viscera* from sharp fragments or loose pieces of bone, or from crushing or tearing. Thus the bladder and urethra, and in the female the vagina, are especially liable to be torn by sharp fragments, and the urethra may be ruptured or compressed, owing to its close relation to the subpubic arch. A vesical calculus has been reported having for its nucleus a piece of bone driven into the bladder in a fracture of the pelvis. It is in the *double fractures* of the pelvic arch that the viscera are most often wounded. In these double fractures the two lines of fracture are most often on one side of the symphysis, rarely on both; or in place of the second fracture we may have a diastasis of the symphysis, which usually occurs, if at all, in connection with fractures of the pelvic arch. The rectum too has been torn or compressed in fractures of the sacrum or coccyx. Information may often be gained for the *diagnosis* of fracture of the pelvis by rectal or vaginal examination, and blood in the urine in such cases indicates an injury to the bladder or urethra. The capsule of the hip joint is almost always external to the line of fracture of the pelvic arch and thus escapes injury.

FIG. 80.

Female pelvis viewed from the left side, showing the position of its parts in the erect posture.  
(JOESSEL.)

In the erect position the *plane of the brim* or outlet of a normal pelvis makes an angle of  $50^{\circ}$  to  $60^{\circ}$  with the horizon, which is due to the sacrovertebral angle and the obliquity of the articulation of the hip bones with the sacrum. This antero-posterior tilting, which we call the *obliquity of the pelvis*, varies in different cases and averages greater in the female than in the male. In hip disease, with ankylosis of the hip joint in the flexed position, the pelvis as a whole moves about the transverse axis passing through the acetabula and its obliquity is increased on standing, in order to bring the ankylosed limb into a vertical position. To allow of this increased obliquity of the pelvis the forward convexity of the lumbar vertebrae is increased (*lordosis*) by their extension. Increased obliquity causes a protrusion of the belly, a flattening of the adductor region, from lengthening of its muscles, and a backward position of the external genitals. The normal obliquity of the pelvis may be shown by placing the anterior superior iliac spines and the pubic spines in the same vertical plane, as against the wall (H. v. Meyer).

The *inclination of the pelvic outlet*, or the angle between the horizon and the line connecting the tip of the coccyx with the lower border of the symphysis, averages  $12^{\circ}$  to  $15^{\circ}$ . The *axis of the inlet*, or the line at right angles to the center of its plane, passes obliquely forward and upward, so that if prolonged it would meet the umbilicus above and the middle of the coccyx below. The *axis of the outlet* prolonged upward touches the base of the sacrum, and prolonged downward is directed slightly backward, whereas the curved line representing the axis of the entire pelvis, if prolonged downward, would curve forward. This distinction is not always understood. The *axis of the cavity*, nearly straight above, more curved below, is parallel to the curve of the sacrum and equidistant from all sides of the pelvis. The descent of the foetal head follows this curved line, turning as it were around the symphysis as an axis. As this curved axis, continued downward, passes near the center of the vulva, those cases where the vulva is unusually far forward are more exposed to rupture of the perineum in delivery. It is also in this curved direction that instruments (sounds, etc.) are passed to the pelvic viscera.

With a normal inclination of the pelvis, the sacral promontory lies  $3\frac{1}{2}$  inches (9.5 cm.) above the upper border of the symphysis and the tip of the coccyx one half to one inch above its lower border. The long axis of the symphysis forms an angle of  $100^{\circ}$  with the conjugate diameter of the brim, *i. e.*, the line between the promontory or sacro-vertebral angle and the upper end of the symphysis. This fact is of importance in obstetrics, as the foetal head makes one of its principal turns around the symphysis.

Obstetricians consider *three diameters*, ventro-dorsal or conjugate, transverse and oblique, in *three planes* of the pelvis, that of the brim, the center or largest part of the cavity, and the outlet. The oblique diameter at the brim is between the sacro-iliac joint and the ilio-pubic eminence, in the cavity from the middle of the sacro-sciatic notch to

the obturator foramen, and at the outlet from the sacro-sciatic ligament to the ischial ramus. The transverse diameter at the outlet is the distance between the ischial tuberosities. The measurements of the diameters vary according to age, sex and individuality, and especially in the presence of pelvic deformities. In the female the conjugate, transverse and oblique diameters measure in inches as follows : at the brim  $4\frac{2}{5}$ ,  $5\frac{2}{5}$ ,  $5 +$ ; in the cavity,  $5 +$ ,  $5$ ,  $5\frac{1}{4}$ ; at the outlet,  $4\frac{2}{5}$ ,<sup>1</sup>  $4\frac{2}{5}$ ,  $4\frac{1}{2}$ . If the measurements are materially diminished symmetrically, as in a case of "equally contracted pelvis," in women apparently well formed, or unsymmetrically in rachitic pelvic deformities, normal labor may be rendered difficult or impossible.

The apparently greater width of the *female pelvis*, as shown by the hips, is due to the greater amount of subcutaneous fat and the comparison with the narrower waist. The distance between the anterior superior spines and the iliac crests of the two sides measures about the same in the two sexes, though many authorities give the latter measurement greater in the female, while Quain gives both greater in the male. The true pelvis is shallower, broader and more capacious in the female; the false pelvis is relatively narrower and less deep in the female (Quain). In the female, too, the symphysis is less deep and both the subpubic arch and the distance between the ischial tuberosities is much wider, all of which are of importance in the mechanism of labor.

The pelvis as a whole may move on three axes, a transverse (flexion and extension), an antero-posterior (tilting), or a vertical (rotation). These movements take place in the lumbar spine. Flexion and extension are the most important and the most extensive, and decrease or increase the obliquity of the pelvis, respectively. When the hip joint is fixed or ankylosed it is the pelvis that is flexed or extended on the transverse axis passing through the acetabula. It is enabled to do this by movements of the lumbar spine in the same direction (see above, p. 351).

Normally the pelvis is on the same level on the two sides so that the line joining the two anterior superior iliac spines is horizontal in the erect position. Pathologically this line may be oblique so that there is a lateral obliquity or *tilting of the pelvis* on an antero-posterior axis. In such a case one side of the pelvis is raised while there is a *lateral curve of the lumbar vertebrae* toward the opposite side to enable the trunk to be held erect. This is often the result of hip disease, where the thigh on the affected side may be fixed in the ad- or abducted position, and the pelvis is tilted to allow the limbs to hang vertically in standing or walking. Or it may result from a shortened limb, from fracture or any other cause, and the length of the two limbs is made apparently and often, for practical purposes, virtually equal by the tilting of the pelvis downward on the side of the shortened limb.

Before illustrating these facts it is well to notice that the *anterior superior iliac spines*, from which we take our measurements to determine the length of the lower extremities, lie lateral to the acetabula. Hence

<sup>1</sup> With the coccyx pressed backward.

we measure the long side of an oblique-angled triangle of which the short side is the line between the iliac spine and the acetabulum, and the third side is the lower limb itself. If the two limbs are of equal length and one is fixed at the hip in the abducted position, the other limb to be parallel with it must be adducted. (Fig. 81, ACM' and A'CM''). By a lateral tilting of the pelvis both limbs are made apparently straight and in the long axis of the body. (Fig. 82.) The pelvis on the abducted side is lowered by the tilting, hence its acetabulum is lower than that of the opposite side. Therefore the limb on the abducted side will appear longer (*apparent lengthening*) than that on the adducted side, which cannot touch the ground. If, however, we measure the two sides we are surprised to find that the abducted and apparently longer limb measures less (*measured shortening*) than the other, while in reality the two are exactly equal in length.

FIG. 81.

FIG. 82.

Figs. 81 and 82. Diagrams to show the correct (81) and the incorrect (82) position for measurement of the lower extremity and the effects of ab- and adduction on the apparent and measured length of the limbs. The plain lines in Fig. 81 show the correct position for measurement, the crossed lines represent the left hand limb abducted, the right adducted. This same position is shown in Fig. 82 but the pelvis is tilted to bring the limbs in line with the axis of the body. A, anterior superior iliac spine; C, coryloid cavity; V, umbilicus; M, malleolus; P, point equidistant from the two malleoli; VP, line from this point to the umbilicus; AA, line connecting the two iliac spines; AM, the line of measurement; CM, the real length of the limb; AC, the line from the iliac spine to the coryloid cavity.

The explanation is simple. As one limb is gradually abducted the triangle, whose long side we measure, approaches more nearly a right-angled triangle until it becomes one, hence the length of the long side we measure decreases as we abduct for, the two sides remaining the same, the long side decreases in length as the angle decreases

from an oblique angle to a right angle and *vice versa*. As the other limb is gradually adducted the obtuse angle in the triangle increases, so that the long side measures more and more until the side representing the limb is in line with the short side of the triangle, and then the line we measure comprises two sides of the triangle which, according to a rule of geometry, are greater than the third side. (Fig. 82, A'CM').

Hence we see that *abduction decreases measured lengthening* and *adduction increases it*. Therefore in measurements to determine the comparative length of the limbs it is necessary to see that there is neither abduction nor adduction. This we do by seeing that there is no tilting of the pelvis and that the limbs are in the long axis of the body or, in practice, that the line connecting the anterior superior iliac spines (Fig. 81, AA') is at right angles to the long axis of the body (Fig. 81, VP) and that the latter prolonged is equidistant from the malleoli of the two feet to which we measure (Fig. 81, MP-PM). Or stretch a string or bandage from the umbilicus to the mid point between the two ankles (Fig. 81, VP) and see that this is at right angles to a line connecting the two anterior superior iliac spines (Fig. 81, AA).

Another anomaly is that if one side is actually a little shorter (*actual shortening*) and the pelvis is tilted, the short limb if adducted may appear shorter and measure longer than the longer limb or, if abducted, it may appear longer and measure shorter. When the pelvis is tilted the limb on the lower side is always abducted and *vice versa*. *Actual, measured and apparent shortening* do not coincide unless there is no tilting of the pelvis. If one limb is a little shorter as a result of fracture of the femur, old hip trouble with loss of substance of the head, excision of the hip or knee joint, etc., it may be *made of equal length* with the other, to all appearances and for all practical purposes, by tilting the pelvis down on the short side and up on the long side. The slightly shorter limb would appear equal but measures considerably shorter. Thus fracture of the femur with an inch or so shortening may be compensated for by such a slight tilting of the pelvis that it is scarcely noticed and produces no awkwardness of gait. The pelvis may also be *rotated on a vertical axis* so that one anterior superior iliac spine is in advance of the other. This may also occur in hip disease.

### The Lining of the Pelvis.

**Pelvic Floor or Diaphragm.**—At the *sides of the pelvis* the ischium, the obturator membrane, and the bony margins bounding it are well padded by the thick obturator internus muscle. At the *back of the pelvis* is the pyriformis on either side, while the *outlet* is occupied by the *coccygeus* behind and, in front of this, by the *levator ani*. These latter two muscles, especially the levator ani, form the *sagging floor or diaphragm* of the pelvis and separate its cavity from the perineum in front and the ischiorectal fossa behind.

The anterior border of the *levator ani* descends along the side of the prostate and some of its fibers unite beneath it with those of the

opposite side at the central tendinous point of the perineum, where they blend with the external sphincter ani and the transversus perinei muscles. The posterior fibers of the levator ani are attached to the tip of the coccyx. The rectum in both sexes and the vagina in the female perforate in the median line the pelvic floor, formed by the levator ani, and at these points the fibers of the muscle interlace with the longitudinal muscle fibers of the walls of those organs, more intimately with those of the rectum. Elsewhere in the median line the levator ani is attached to the median fibrous raphé, extending from the coccyx to the rectum and thence to the central tendinous point of the perineum.

Besides the openings for the rectum and vagina there are several *small openings* in the pelvic walls *for the passage of vessels and nerves*: (1) through the *great sciatic notch*, above the pyriformis, for the superior gluteal vessels and nerves; (2) through the great sciatic notch between the pyriformis and the coccygeus for the internal pudic and sciatic vessels and nerves and the inferior gluteal vessels; (3) through the *obturator foramen* above the internal obturator muscle for the obturator vessels and nerves. The gap in the pelvic floor between the levator ani muscles in front is filled by the triangular ligament, which is pierced by the urethra and, above it, by the dorsal vein of the penis, or the corresponding vein in the female.

**Pelvic Herniæ.**—Through the first two foramina above mentioned two of the forms of pelvic herniæ occur.

**Obturator hernia** occurs through the *obturator canal*, which is directed downward, forward and inward beneath the horizontal ramus of the pubis for about 2 cm., with a diameter of 1 to  $1\frac{1}{2}$  cm. Such a hernia pushes a sac of pelvic peritoneum before it and sometimes the obturator fascia. It comes to lie deeply beneath the pectenous and adductor longus muscles, by separating which it may be exposed through an incision near the inner border of Scarpa's triangle. It is often best to reach it by abdominal incision above the pubes. The *obturator vessels and nerves* are usually on the outer side or, next most commonly, the nerve may be in front and the artery behind. The proximity of the nerve renders peripheral pain from pressure a conspicuous symptom, which has misled surgeons into treating it for some other condition. As the hernia lies on the mesial side of the hip capsule pain on moving the hip is often a marked symptom. Obturator herniæ generally occur in advanced age and much more commonly in females, in whom, it is well to note, the inner orifice of the canal can be examined through the vagina. It is too deeply situated to be evident in Scarpa's triangle and may best be detected by the finger along the pubic ramus and behind the adductor longus, while the thigh is flexed, adducted and rotated out, or by vaginal or rectal examination. Strangulation is the rule.

**Ischiatic hernia**, escaping through the great sciatic foramen, above or below the pyriformis, lies beneath the gluteus maximus muscle. It is rare.

Other rare forms of herniæ occur through the pelvic floor, whose starting point we know only imperfectly. They occur in adults, usually in women, and on one side of the median line. The sac, covered by the rectovesical fascia, escapes through the fibers of the levator ani muscle to appear in the posterior part of the labium majus (*pudendal hernia*), in the perineum (*perineal hernia*), in the ischiorectal fossa (*ischiorectal hernia*) or in the vagina (*vaginal hernia*). A rare form of hernia, whose sac is covered on one side by the rectal wall, may appear outside of or just within the sphincter ani muscle (*rectal hernia*). In perineal hernia the sac escapes in front of the rectum between it and the vagina or prostate, and in pudendal hernia it escapes between the ischial ramus and the vagina.

**Pelvic Fascia.** (Fig. 84.)—The muscles of the walls and floor of the pelvis are lined by a fascia, the pelvic fascia. This helps to form a sheath for the muscles and to separate more effectually the pelvic cavity from the perineum and ischiorectal fossa, and it serves to strengthen and support the pelvic viscera by its reflections onto them. Certain parts of these reflections onto the viscera are called their *true ligaments*, in the case of the bladder, etc. Two principal portions are distinguished, a parietal and a visceral.

The parietal portion, or **obturator fascia**, lines the obturator internus and is *continuous with* the iliac and transversalis fasciæ at the pelvic brim, along which it is attached. It is also *attached to* the free border of the ischium, the falciform process of the great sacrosciatic ligament, and the inner lip of the lower border of the ischiopubic ramus. At the latter attachment it is continuous on either side with the deep layer of the triangular ligament. The obturator fascia forms a fibrous canal for the internal pudic vessels and nerves. Along a line from the back of the pubis to the ischial spine the levator ani is attached to this fascia, which is here thickened and hence appears white (the *white line*). The obturator fascia above this line is sometimes distinguished as the “*pelvic fascia*.”

From this white line is given off the visceral portion, or **rectovesical fascia**, which lines the upper or pelvic aspect of the levator ani muscle and is *reflected onto* the pelvic viscera where they penetrate this muscle, *i. e.*, rectum and vagina, and onto those immediately related to the pelvic floor, bladder, prostate, seminal vesicles and uterus. From the lower end of the bladder it is reflected down to form the *fibrous capsule of the prostate*, at the apex of which it is continuous with the deep layer of the triangular ligament. It thus encloses the vesicoprostatic plexus of veins. From either side of the symphysis a fold of this fascia, covering a small bundle of muscle tissue prolonged from the bladder (vesicopubic muscle), passes back to the prostate and bladder as the anterior true ligaments of the bladder (*puboprostatic ligaments*). In the depression between the latter the pelvic fascia is thin and through it is seen a plexus of veins, connected with the dorsal vein of the penis, which lies beneath the plexus. The fold from either side of the pelvis to the sides of the bladder, the lateral true ligaments of the bladder, are

# PLATE XLI.

FIG. 88.

Pelvic floor in the male. The fascia is in place on left and is removed on right side. The dotted line outlines the bony outlet of the pelvis. (Testut.)

FIG. 84.

Frontal section of the pelvis through the middle of the ischiopubic rami; partly diagrammatic, to show the pelvic fasciæ. Anterior segment of the section viewed from behind. The fasciæ are in blue. (Testut.)

scarcely demonstrable. Further back the fascia passes across between the bladder and rectum, uniting yet separating them in the trigonal area and investing the seminal vesicles. The lower end of the rectum also receives a thin prolongation of the fascia.

Behind the levator ani the rectovesical and obturator fasciae are continuous and cover the pelvic aspect of the coccygeus and pyriformis muscles. At the anterior border of the levator ani the rectovesical fascia above it joins the anal fascia beneath it and is continued forward to the obturator fascia, or its prolongation the deep layer of the triangular ligament.

The reflections and attachments of the rectovesical fascia *exclude certain viscera*, or parts of viscera, from the pelvic cavity, i. e., the prostate, seminal vesicles, trigone and outlet of the bladder and the lower  $2\frac{1}{2}$  to 3 inches of the rectum. These may be wounded without entering the pelvic cavity and, provided their fascial sheath is intact, suppuration in them would tend to spread towards the perineum and not into the pelvis. On the rectum the fascia reaches some little way below the rectovesical pouch of peritoneum in front. The *pelvic vessels* are on the inside of the fascia, the *nerves* of the sciatic and lumbar plexuses on the outside. The vessels, excepting the obturator, must pierce the fascia to get out of, the nerves to get into the pelvic cavity and through these small openings inflammation may possibly spread. But as a rule *suppuration above the fascia* is limited to the pelvic and abdominal cavity, that below to the perineum and ischiorectal fossa. Wounds of the latter two regions that involve this fascia have the added danger of pelvic inflammation ; hence is seen the surgical importance of the pelvic fascia.

Between the *peritoneum*, which lines part of the pelvic floor and covers most of the pelvic viscera, and the "pelvic" and rectovesical fasciae is a continuous layer of loose *subperitoneal connective tissue* in which inflammation may spread readily and widely and lead to suppuration. This tissue is found *most abundantly* between the anterior bladder wall and the pelvis and about the outlet of the bladder and, in the female, about the lower part of the uterus and the upper end of the vagina and between the folds of the broad ligament. Inflammation and suppuration in this tissue, known as *pelvic cellulitis*, is prevented from escaping through the pelvic floor by the pelvic fascia. Hence, as this tissue is continuous with the subperitoneal tissue of the iliac fossa, the *abscess* usually passes up over the pelvic brim to the iliac fossa and *points* in the inguinal region (q. v.). Rarely it may open into one of the pelvic viscera or into the peritoneal cavity. In the male it may follow the vas deferens to the inguinal canal and scrotum. In women the inflammation and abscess are often found within the broad ligaments or beneath the peritoneum lining Douglas' pouch, between the uterus and rectum. Clinically pelvic cellulitis is often accompanied by an inflammation of the pelvic peritoneum, *pelvic peritonitis*; the latter may also occur separately.

In *pelvic hematocoele* the blood, if *intraperitoneal*, may trickle into Douglas' pouch, where it may become enclosed by peritoneal adhe-

sions; or, if *subperitoneal*, it collects most often between the layers of the broad ligament. It often comes from a ruptured varicose ovarian vein. Pressure of the mass on the rectum may cause tenesmus. These collections of blood may of course become infected and suppurate and in such a case can be opened through the vagina.

## THE VISCERA OF THE PELVIS.

### The Rectum.

As stated above (see Sigmoid Flexure, p. 317) that part of the rectum, formerly called the first portion, which is provided with a mesentery and extends from the left sacro-iliac joint, at the pelvic brim, to the middle of the third sacral vertebra, is now considered as a portion of the sigmoid loop, with which it is continuous. Between the layers of the mesentery of this portion of the sigmoid run the *inferior mesenteric vessels* which *divide*, where the mesentery ends, into the two sets of bilateral *superior hemorrhoidal vessels*.

The rectum thus limited is more entitled to its name, rectum (straight), as it is not curved laterally, only antero-posteriorly. Of the *two parts* into which it is naturally divided the *upper or pelvic portion*,  $3\frac{1}{2}$  inches long, follows the curve of the sacrum and coccyx, upon which it lies; the *lower or anal portion* bends backward and downward just below the tip of the coccyx. It is important to bear in mind the *direction of the two curves* in examining or passing instruments into the rectum. The *axis of the anal portion* if continued meets the prostate near its apex or the rectovaginal septum. Hence, in introducing a bougie, the nozzle of a syringe, a speculum, etc., the instrument should first follow the axis of the anal portion for  $1\frac{1}{2}$  inches, upward and forward, and then be tilted so that its upper end is directed upward and backward in the curve of the upper part.

The *dividing line* between these two parts corresponds about to the point where the rectum pierces the pelvic floor. The anal portion is therefore entirely extra-pelvic and, by the manner of the reflection of the pelvic fascia (see above, page 357), the lower part of the upper portion is also extra-pelvic. In infants the lower end of the large gut is straighter and more or less vertical, and the upper part of what was formerly called the first portion of the rectum is in the abdominal cavity. On account of its more vertical position in childhood, together with its loose connections, the small size of the prostate and the liability to such exciting causes as worms and rectal polypi, *prolapsus ani* is especially common at this age.

**The Pelvic Portion.**—Above the anal portion the rectum is dilated into a large *ampulla* extending forward to the apex of the prostate, and backward to the coccyx. This part is very *distensible* and, in cases of faecal accumulation, may be enormously distended. Curious *foreign bodies* of large size have been found in this ampulla such as, for instance, a bottle (Desormeaux), a glass tumbler and an iron match box. When this portion of the rectum is *distended* in the male,

*the bladder is raised* and pushed forward and the rectovesical pouch of peritoneum is elevated. Advantage has been taken of this fact in *suprapubic cystotomy* by distending the rectum by a rubber bag, inflated with air or water, to help raise the bladder above the symphysis.

This portion is *large enough to contain the entire hand* which may be introduced, if not over eight inches in diameter, after a gradual dilatation of the sphincters under anaesthesia. By a semi-rotary movement it can be insinuated into the lower end of the sigmoid loop. It is said that a large part of the abdomen may be thus examined, even as far as the kidneys, owing to the movability of the part. Yet the *practice is dangerous* as the bowel may be torn, especially that part covered by peritoneum, and the sphincter may be permanently paralyzed. Moreover the practical results are unsatisfactory owing to the cramping of the hand. By means of a wooden lever, invented by Mr. Davy, introduced into the rectum, the common iliac vessels have been compressed against the pelvic brim to arrest hemorrhage in amputation at the hip joint.

**Attachments.**—Although the rectum, in passing through the pelvic floor, receives an attachment from the pelvic fascia, this fascia is not so firm but that in rare cases all the walls of the gut are prolapsed at the anus. This *mobility* of the rectum is *of use in excision* of its lower part, for it allows the upper part to be drawn down so as to be sutured to the skin or the edges of a healthy anal segment. In order to *free it for removal* the *levator ani muscle*, some of whose fibers are prolonged into and support the bowel, is divided. To allow the upper part to be pulled down the *peritoneal attachment* must be loosened. This may be done by carefully stripping up the peritoneum from off the front and sides of the rectum and then by dividing the mesentery of the lower sigmoid on either side, taking care to avoid the blood vessels, which run superficial to the muscle layers, for injury to these vessels means gangrene of the upper segment.

The rectum is loosely *attached by loose connective tissue* to the lower half of the sacrum and the coccyx, while in front it is more *closely attached* to the back of the prostate and bladder by firmer connective tissue, the *prostato-peritoneal aponeurosis*, connected with the rectovesical fascia. This aponeurosis however allows the separation of the rectum from the prostate and bladder and, if traced upward, is found to be attached to the bottom of the rectovesical pouch of the peritoneum. *In the female* the rectum is attached to the vagina in front by a considerable amount of looser connective tissue.

**The relations** of the rectum have a twofold importance, first in diseases of or operations on the rectum, second because rectal examination is of the greatest importance in determining the condition of the organs in relation to it.

**Relations to the Peritoneum.**—Commencing opposite the third sacral vertebra there is no mesorectum but the peritoneum, at first covering the front and sides of the bowel, is reflected from the sides along an oblique line descending from behind forward. It is finally

reflected from the front of the rectum onto the bladder in the male and onto the vagina, cervix and uterus in the female, forming the *rectovesical* and *rectovaginal pouch* (Douglas' pouch) respectively. The distance of the rectovesical pouch from the anus is of importance in rectal operations and measures 3 inches, or somewhat more, when the bladder is empty, and as much as 4 inches when it is full. The distance of the similar pouch in the female (Douglas' pouch) from the anus is somewhat less.

In complete prolapse of the rectum of large size this peritoneal pouch may be protruded and may contain coils of intestine, which occupy it in the normal condition. On the posterior rectal wall the peritoneum does not come within five inches of the anus. Thus ulcers and carcinomata situated anteriorly are more likely to invade the peritoneal cavity and, in excisions of the rectum, more of the bowel may be readily excised posteriorly than anteriorly. But, as we have seen, in the absence of inflammatory adhesions we may detach from the peritoneum and draw down the rectum as far as the commencement of the mesentery, where the peritoneum encloses the bowel. Above this point the bowel may be freed by dividing the peritoneum of the mesentery on either side, taking care not to injure the blood vessels.

By rectal examination in the female we can feel anything abnormal, like a prolapsed ovary or a retroflexed uterus, occupying Douglas' pouch, or, in the absence of these, we can feel the uterus in front and the ovaries at the sides, if the latter are enlarged or displaced. The retroflexed or retroverted uterus may so press upon the rectum as to favor constipation, cause tenesmus, and set up inflammatory or congestive conditions in the rectum and an adhesion of the opposed peritoneal surfaces of the pouch. The close relation of the vagina and anterior rectal wall accounts for the tears into the rectum at childbirth. The foetal head has occasionally been forced through the thin rectovaginal wall and delivered per rectum.

Below the rectovesical pouch in the male we can feel the bladder, corresponding to the trigone, judge of its distension and occasionally feel a calculus when present in the bladder. Through the triangular area of the bladder in contact with the rectum, and below the peritoneal pouch, the distended bladder was formerly punctured by a trocar but, owing to the danger of infection, this method has been superseded by the suprapubic puncture. Bounding the two sides of the triangular area are the seminal vesicles and the vas deferens. These can be readily felt when diseased (tubercular) or distended, not readily when normal. In violent attempts at defecation they may be pressed upon by the fecal masses and partly emptied, producing a mechanical form of spermatorrhoea. Massage of the seminal vesicles as a therapeutic measure has been practiced through the rectum. A stone impacted in the lower end of the ureter may possibly be felt through the rectum.

Below the palpable area of the bladder and seminal vesicles we readily feel the posterior surface of the prostate whose apex,  $1\frac{1}{2}$  inches from the anus, is in front of the ampulla at the lower end of the upper

## PLATE XLII.

FIG. 85.

Sagittal section of the lower part of a male trunk, the right segment. (Gerrish, after Testut)

portion of the rectum. By rectal palpation we can feel the changes of size, shape, consistency and sensitiveness in hypertrophy, inflammation and abscess of the prostate. The *enlarged prostate* naturally *projects into the rectum* and, when of very large size, may cause obstruction to the passage of feces. We can thus appreciate why defecation is painful in prostatitis, etc. At this part too a *prostatic abscess may open into the rectum*, and such an opening may result in a urethrorectal fistula.

Below and in front of the apex of the prostate can be felt the membranous urethra especially when occupied by a sound. The forefinger in the rectum with its tip at the apex of the prostate is used as a guide in Cock's operation (perineal section), and is useful in many perineal operations on the urethra, prostate, etc., and even in passing a urethral instrument in difficult cases.

The bony points palpable by rectal examination have been mentioned (p. 346). Their palpation is of use in determining the presence of any fracture, disease or new growth connected with them. It is well to remember, in examining for suspected lesions high up in the rectum, that by having the patient strain as at stool, especially in the standing position, one to two inches more of the rectum can be palpated than otherwise.

The rectum is *not properly a reservoir for feces*, and in the healthy condition the presence of the latter stimulate it to contract. In some cases, especially those subject to habitual constipation, it may contain a large amount of feces, as often made out by digital examination, the nerves and muscles having become degenerate and ceasing to act.

**The anal or terminal portion**  $1\frac{1}{2}$  inches long, is the *narrowest* part of the large intestine though very *dilatable*. It is quite distinct in its surgical relations from the pelvic portion. The internal sphincter surrounds it while the levator ani and its enclosing fasciæ are attached to and support its sides, which are in relation to the ischiorectal fossæ. In front lies the perineal body in the female, separating it from the lower end of the vagina, and the perineum in the male, separating it from the urethra. In the female the urethra is separated from it by the vagina and perineal body.

In the male the anal portion forms the posterior wall of a triangle of which the perineum forms the base and the membranous portion of the urethra, where it adjoins the rectum, the apex. Through this triangle are made the various perineal incisions by which the bladder or posterior urethra, and sometimes the prostate and seminal vesicles, are reached.

**Structure of the Rectum.**—The *longitudinal muscle fibers* are more uniformly spread out than in the rest of the large intestine though, according to some, the three bands are continued as two bands, one in front and one behind, which broaden as they descend. The *circular fibers* are abruptly thickened (to 3 or 4 mm.) in the upper inch of the anal portion to form the *internal sphincter*. The *lower limit* of the anal portion is represented on its interior by a circular "white line" which

marks the junction of the skin and mucous membrane. The *external sphincter*, surrounding the anal orifice, is a striped or voluntary muscle.

The looseness of the *submucous* tissue is such as to allow the mucous membrane to be protruded or *prolapsed* at the anus on prolonged straining at stool or micturition. The greater looseness of this tissue in infants and children and the frequency of straining attending phimosis, constipation or the irritation of worms and polypi, makes this accident especially *frequent in early life*. It may also be due to the relaxation of the parts attending persistent diarrhoea. When small it involves only the mucous membrane and tends to re-ascend, but may be held down by an irritated sphincter. When large all the coats of the bowel are apt to be involved and the rectovesical peritoneal pouch, and even coils of intestine, may be contained in the prolapse.

Certain obliquely transverse folds of mucous membrane, "Houston's folds" or "valves," not effaced by the distension of the rectum, are of importance, for they may *impede the passage of a bougie* or a rectal tube, especially if the rectum is empty. Hence in giving a high enema first fill the rectum with fluid and then these folds will not impede the passage of the tube. Three such folds are usually present. One, the largest, on the right and anterior aspect is near the rectovesical pouch of peritoneum, or about 3 inches from the anus, and projects  $\frac{1}{2}$  to  $\frac{3}{5}$  inch into the lumen of the gut, extending around half of its circumference or more. It has been described as the third or upper sphincter. The other two are to the left, above and below the former, and the three are so arranged as to form a kind of spiral valve.

In the anal portion, commencing just above the orifice, are several (3 to 8) *longitudinal columns* or folds of mucous membrane,  $\frac{1}{2}$  to  $\frac{1}{2}$  inch long, due probably to bands of the muscularis mucosæ. Between the lower ends of these columns are semilunar folds or valves whose upturned concavities form little *sinuses*. These are the *columns, valves and sinuses of Morgagni*. Upon these columns are to be seen little protrusions, due to hemorrhoidal veins.

The mucous membrane is liable to *dysenteric inflammation and ulceration* and the cicatrization of the ulcers may produce *stricture*. The liability to ulceration is greater the nearer the anus. As the epithelium of the anus is squamous and that of the rectum columnar an *epithelial neoplasm* of the former is an epithelioma (squamous celled carcinoma) and of the latter a carcinoma or columnar epithelioma.

**Vessels.**—The arteries of the rectum are *from three principal sources*, the inferior mesenteric, the internal iliac and the internal pudic. The branches of the two lateral trunks of the superior hemorrhoidal pierce the muscular wall about three inches from the anus to form a *longitudinal network* in the *submucous* tissue. Hence *incisions* here should be lengthwise to avoid profuse bleeding. The arteries *communicate* freely in a plexiform manner near the anus and more or less above. Although the *veins* have the same plexiform arrangement in the *submucous* tissue of the lower rectum and take the same course, *most of the blood is returned by the superior hemorrhoidal* to the inferior

mesenteric vein. Hence congestion of the so-called hemorrhoidal veins of the rectum is apt to follow portal congestion as well as venous congestion due to diseases of the heart, lungs, etc.

In addition to these causes the tendency to varicosities of the hemorrhoidal veins, **hemorrhoids or piles** is *in part due to* their dependent position, the want of valves, and the pressure of fecal masses, etc. They may also be symptomatic of pregnancy, ovarian or abdominal tumors, stricture of the rectum, prostatic enlargement, etc., as all of these conditions may obstruct the return of venous blood. These veins also communicate with those of the prostate and bladder.

Hemorrhoids usually *commence* close to the point where the superior and inferior sets of veins anastomose, *just within the anal orifice*, where the *ano-rectal groove* is produced by the distension of the internal or superior veins above it and the external or inferior veins below it. Both sets of veins are usually simultaneously involved, but when the internal or external set is exclusively or predominantly involved the varicose enlargement is called *an internal or external hemorrhoid* respectively. A series of such swellings often surrounds the outlet of the bowel. Piles are usually confined to the submucous or subcutaneous tissues so that they are *covered only by the mucous membrane* (internal piles) or *skin* (external piles). The mucous membrane or the skin on the surface of the swelling, due to the dilated and sometimes thrombosed veins, is chronically inflamed. The mucous membrane may be thickened, thinned or ulcerated, in the latter case leading to "*bleeding piles*"; the skin is usually thickened, and develops into a flabby tab when acute inflammation is absent.

It should be borne in mind that the lower rectum thus furnishes an important *anastomosis* between the portal and caval veins.

**The nerve supply** of the rectum is from the inferior mesenteric and hypogastric sympathetic plexuses and the sacral plexus (fourth sacral nerve). The latter accounts for the paralysis with incontinence of feces that follows spinal injuries or diseases in the lumbar region or above. It is also mainly responsible for the close nervous association between the anus and the outlet of the bladder, which is supplied by the same nerve, so that on the one hand painful affections of the former may cause a frequent desire to urinate and operations on the anus are especially apt to be followed by temporary retention of urine; and on the other hand lesions of the outlet of the bladder are often associated with tenesmus. *The anus is supplied by* the internal pudic nerve, which accounts for the wide distribution of reflex pain in anal fissure. The *upper part of the rectum is but little sensitive* as illustrated by the comparative painlessness of new growths and the passage of instruments high up in the rectum. On the other hand the last two inches of the bowel are extremely sensitive.

**The lymphatics** of the rectum enter the pelvic and lumbar nodes, those of the anus the inguinal nodes. Thus the anus has a blood, nerve and lymphatic supply independent of that of the rectum.

The **anus** is an *oval*, not a circular, orifice at the lower end of the anal portion of the rectum. Hence specula, etc., should be introduced with the long diameter antero-posteriorly in the long axis of the anus. The anus *lies* in the median line  $1\frac{1}{2}$  inches in front of the coccyx, midway between the two ischial tuberosities and only slightly further from the lower border of the symphysis than from the tuberosities. In health it is tightly closed and, radiating from its margins, there are numerous puckerings or small folds of skin, between which **fissures** or **ulcers** of the anus form and are often hidden. The *painfulness* of this affection is due to the reflex contraction of the sphincter, compressing the exposed nerve fibers at the base of the fissure or ulcer. Hence *dilatation of the sphincter*, thereby temporarily paralyzing it and tearing the base of the fissure, gives relief and affords the fissure a chance to heal. Incision of the base of the ulcer, so as to divide part of the sphincter, produces a similar result. The anus may be torn by large hard stools during defecation and some such tears may result in "painful fissure."

Near the anus we see the *external opening* in cases of **fistula in ano**. The most common form is the result of *marginal abscesses*, superficial to the sphincters and lying merely beneath the skin and mucous membrane. Their *internal orifice* is generally found a little above the "white line" (mucocutaneous junction) just within the grasp of the sphincter. The *upward extension* of an ischiorectal abscess is resisted by the levator ani, between which and the external sphincter it finds a point of least resistance to extend toward the rectum, into which it opens just above the external or internal sphincter. The abscess before opening may extensively undermine the mucous membrane, so that the resulting fistulous tract may extend upward way above the internal opening. Tillaux describes a form of fistula which may apparently heal but again breaks out on the same or the opposite side, and which he attributes to a hard *semilunar valve-like fold* at the upper end of the rear wall of the anal portion. Division of this stricture-like fold results in a cure of the fistula, whose internal opening is above the level of this fold.

*Inspection of the anus is of diagnostic importance.* Thus in cases of obstruction due to stricture of the rectum, greatly enlarged prostate, etc., the anus is patulous and flabby, while in fissure it is tightly closed.

**Development and Errors of Development.**—The *pelvic portion* of the rectum is formed by the blind caudal end of the hind gut, the *anal portion* by an invagination of the surface at the site of the anus. Normally the *septum between them* is absorbed so as to form a continuous canal, but abnormally it may leave an annular constriction an inch or so within the anus or it may persist and form an **imperforate anus**. In such cases the *septum persists* (1) as a *thin membranous septum* which bulges with the retained meconium and may be readily incised, or (2) as a *thicker partition* after division of which the rectal mucous membrane must be brought down to the surface. Again, there may be no anal pouch whatever, and in such cases the lower end of the rectal portion may or may not be deficient. In infants with obstinate con-

stipation digital examination of the rectum must not be neglected. If a careful dissection through a median incision prolonged back to the coccyx and carried up to the front of the coccyx and sacrum fails to discover the rectal pouch an inguinal colostomy must be made.

*In rare cases the rectum opens cutaneously at some unusual point* (symphysis, prepuce, perineum, sacral, gluteal or lumbar regions) and usually by a long canal with a narrow aperture. More often it opens into the genito-urinary tract, bladder, urethra, or vagina. Primarily the allantoic vesicle, from which the bladder and the posterior urethra are formed, was derived from and opened into the hind gut. The persistence of this connection may explain the rare opening between the rectum and the bladder. The rectal pouch in such cases lies so high up that inguinal colostomy must be resorted to. The opening into the bladder or urethra is usually small and requires operative relief if possible. I have seen the opening into the vagina sufficient for the purposes of defecation, and this condition has been often reported. In the latter case operation should be deferred until after puberty, when the increased size of the pelvis and perineum facilitates a plastic operation. Women have even married and borne children with a vaginal outlet to the rectum and without inconvenience from the latter.

**In operations** for the removal of neoplasms or for resection of strictures of the rectum room may be gained and the exposure of the parts increased by excising the coccyx, after incising back to the sacrum. Or, following Kraske's method or one of its modifications, the lower end of the left half or both halves of the sacrum may be permanently or temporarily resected (osteoplastic method). In these operations the lower border of the third sacral foramen should be the upper limit of the resection of bone, for if it is carried higher there is a risk of permanent paralysis of the bladder from interference with the third sacral nerves. These operations are carried out on the left side, for it is on that side that the lower or pelvic portion of the sigmoid loop lies. By division of the sacro-sciatic ligaments or resection of their sacral attachments the entire sacro-iliac notch is opened up. When possible it is advisable to save the anal portion, containing the sphincters, and use it by suturing the upper segment to it.

### The Bladder.

The shape, position and relations of the bladder, or urinary reservoir, depend upon age, sex, and the degree of distension of the organ. The average capacity is about a pint (400 to 500 c.c.) but may reach 1,000 c.c. under normal conditions. When distended, in cases of retention, etc., the bladder has held as much as 3,000 to 4,000 c.c. of urine, and Tillaux reports a case in which it held 7 liters (7,000 c.c.). On the other hand a contracted bladder may contain no more than 10 to 20 c.c. The bladder of the male is somewhat more capacious than that of the female.

**Shape and position** of the adult male bladder. *The form of the empty bladder* is a disputed point. Two forms are described: (1) the *systolic*

or contracted form, in which the bladder represents a firm oval whose cavity, on sagittal section, forms with that of the urethra, a continuous curved slit, and (2) the diastolic or relaxed form, in which the upper aspect presents to the intestines a cup-shaped concavity and the cavity, with that of the urethra, presents a Y-shaped fissure on sagittal section. It is probable that the systolic form is the common one during life.

When moderately filled it is entirely within the pelvic cavity and has a rounded form, which may be flattened or transversely elongated by the pressure of the adjoining viscera. As it becomes distended it becomes oval, the convexity of the superior and postero-inferior surfaces is increased, the anterior surface is flattened and its upper part, rising out of the pelvis, is in contact with the back of the anterior belly wall. This fact is taken advantage of in suprapubic cystotomy and tapping. In distension the upper or smaller end comes more and more in contact with the anterior belly wall and may reach the umbilicus and even, it is said (Tillaux), the diaphragm. The distended bladder is not quite symmetrical but deviates slightly to the right, owing partly to the rectum on the left side and partly to the greater size of the right half of the bladder. When distended so that its upper end is at the upper margin of the symphysis, its long axis is directed from the latter point to the end of the coccyx.

The vesical outlet (or internal urinary meatus) is on a horizontal line a little below the center of the symphysis, about an inch behind the latter and 2 to  $2\frac{1}{2}$  inches above the perineum. In distension the bladder is displaced downward as well as upward, displacing the perineum so that its outlet is at a somewhat lower level, while in cases of prostatic enlargement the outlet may be displaced upward, even above the symphysis.

The bladder lies behind the anterior pelvic wall, in front of and above the rectum in the male, the cervix uteri and the upper end of the vagina intervening in the female, and in contact with the small intestines and the sigmoid loop above and behind.

**Relations to the Peritoneum.** (Figs. 85 and 87.)—The peritoneum covers the entire superior surface, the lateral surfaces down to the line of the obliterated hypogastric artery, or a line extending from the urachus to a point somewhat below the summit of the seminal vesicles, and the upper part of the posterior surface, to the bottom of the rectovesical pouch. This pouch is usually filled with convolutions of the small intestine, separating the bladder and rectum, and it reaches to a point just below the upper ends of the seminal vesicles and about an inch above the prostate (three inches from the anus). It forms the upper limit of the triangular area over which the rectum and bladder are closely adherent.

Normally the peritoneum lines the anterior abdominal wall down to the symphysis pubis, from which it passes onto the upper end and superior surface of the bladder. As the distended bladder rises above the pelvis it pushes up this parietal peritoneum which thus comes to cover the upper half of that part of the anterior bladder surface which

extends above the symphysis, while the lower half of this surface is in direct contact with the anterior belly wall, just above the symphysis, without the intervention of the peritoneum. It is this arrangement of the peritoneum that renders suprapubic cystotomy or tapping a feasible and safe operation, for we can thus puncture or open a distended bladder above the symphysis without opening the peritoneum. Exceptionally the peritoneum is adherent to the pubes so that it cannot be pushed up by the bladder. In operating on such a case wounding of the peritoneum would be likely, but this wound could be sutured, the peritoneum carefully detached below and drawn upward, and the bladder then opened.

Theoretically the lower half of that part of the anterior bladder surface above the symphysis should be devoid of peritoneum no matter how high the bladder rises, but practically there is seldom more than 2 or  $2\frac{1}{2}$  inches between the symphysis and the peritoneum, though the latter can be retracted still further upwards. When the bladder reaches half way from the symphysis to the umbilicus there will be this 2 or  $2\frac{1}{2}$  inches of the anterior abdominal wall above the symphysis devoid of peritoneum and in direct contact with the anterior bladder wall. The use of Petersen's rubber bag, inflated in the rectum, prevents the bladder, filled with 8 ounces of fluid, from extending downward and backward toward the perineum, and at the same time directly raises it and thus helps to bring it in contact with the anterior belly wall, but it has no special influence in raising the peritoneal fold above the symphysis. By the use of Trendelenburg's position gravity tends to bring the moderately filled bladder above the symphysis pubis and in contact with the anterior abdominal wall, so that I have discarded the rectal bag as unnecessary. In fact I have found little difficulty in opening the empty bladder, supra pubes, by the use of the Trendelenburg position.

The anterior surface and that part of the *lateral surfaces below* the limit of the peritoneum is separated from the obturator and levator ani muscles, of the anterior and lateral pelvic walls, by a quantity of *loose areolar tissue* whose meshes contain much fat. This tissue ensheathes the vesical vessels and occupies an area (*cavum Retzii*) more or less triangular, with its base directed downward, and shut in by the peritoneum above. The *looseness of this tissue* readily allows changes in dimension without disturbing the connections of the bladder, and it also *favors the rapid and wide spread of inflammation* following wounds of the bladder with extravasation of urine. This tissue separates the distended bladder from the anterior abdominal wall, below the fold of the peritoneum. Hence it is *opened up in suprapubic cystotomy* and traversed by a trocar in tapping the bladder so that suppuration in this tissue, and in rare cases death, has followed the latter procedure. This tissue is also *continuous above and at the sides, with the abdominal and pelvic subperitoneal connective tissue*, hence an inflammation in it may become widely diffused.

**The ureters pierce the bladder** (Fig. 87) at the junction of the lateral and posterior surfaces, about  $1\frac{1}{2}$  inches from each other and the

same distance above the prostate; just above the outer and upper limits of the triangular area of vesicorectal contact; near to, though not in contact with, the rectum, so that a calculus in the lower end of the ureter may possibly be palpated through the rectum. The *vasa deferentia* cross the lateral bladder wall from before backward and above downward to reach the inner side of the seminal vesicles and form the sides of the above-mentioned triangular area on the posterior vesical surface. They cross the obliterated hypogastric arteries, and thence to the above triangular area they lie subperitoneally. They pass between the bladder and the ureters just where the latter pierce the bladder.

**Rupture of the bladder** is more serious when it involves in whole or in part the portion covered by peritoneum. Violence applied to the anterior belly wall may rupture the distended bladder without fracture of the pelvis or any external sign of injury. The bladder may be torn by bony fragments of a fractured pelvis or, rarely, in case of an injury of the rectum or vagina. When the bladder is distended by urine, in neglected cases of stricture, the urethra gives way as a rule before the bladder and the urine is extravasated into the perineum. But rupture of the viscus has resulted in some cases from congenital closure of the urethra in infants and in neglected cases of retention of urine, especially in women. When the bladder is artificially over-distended it usually gives way laterally, below the peritoneal reflection (Tillaux), but most ruptures intra vitam involve in part, at least, the surface covered by peritoneum, for it is this part that is most distended when the bladder is filled. In intraperitoneal ruptures urine is extravasated into the peritoneal cavity which it does not irritate if normal and fresh, but when abnormal or after becoming stagnant. Hence a primary condition of treatment is the free drainage of the bladder and hence also the fatality of such ruptures unless the rent is repaired by suture and the extravasated urine is removed from the peritoneal cavity. The *injury is indicated by* inability to urinate, the urine passing through the rent into the peritoneal cavity, by the catheter removing only a little blood-stained urine, and by only a part of the fluid injected returning by the catheter. If the rupture is extraperitoneal the urine escapes into the loose cellular tissue of the cavum Retzii and cellulitis and abscess results, though recovery often ensues. Stab or bullet wounds take the same course according as they are intra- or extraperitoneal, except that a small bullet wound, like the puncture of a small trocar, may become at once plugged by the mucous membrane and the muscular contraction of the wall, thus preventing extravasation.

**Fixation of the Bladder.**—The reflections of peritoneum onto the bladder, known as its *false ligaments*, steady it without fixing it, while the bands of thickened rectovesical fascia, reflected onto its base and known as its *true ligaments*, anchor this part. It is still further fixed in position by its attachment behind to the rectum in the male and the uterus and vagina in the female, and by the connection of the ureters, urethra, prostate and the fibro-muscular cord of the urachus.

**Malposition.**—In spite of these various means of anchoring the bladder it has been *found in* inguinal, femoral, vaginal and other forms of pelvic hernie. In inguinal and femoral herniae the part herniated may be entirely extraperitoneal, or in part intraperitoneal. An abnormally high position of the bladder may be due to prostatic, rectal or pelvic tumors.

The bladder wall varies in thickness from one eighth inch, when moderately distended, to one half inch or more when contracted. The anterior wall and trigone are somewhat thicker than the rest of the bladder. When there is obstruction to the escape of urine the *bladder muscle hypertrophies* from undue exercise, like other muscles. In such cases the interlacing network of the internal layer of fibers is thickened and appears as distinct intersecting ridges beneath the mucous membrane (*the fasciculated bladder*). The bladder wall in the interspaces of this network is thinner and weaker, and its mucous membrane may become protruded or herniated in the form of sacculi, by the increased intravesical pressure (*the sacculated bladder*). One or several of these sacculi may become so enlarged as to allow urine to stagnate and decompose, phosphatic deposits to form and collect, and calculi to develop or become hidden (*encysted calculi*). When a calculus, previously contained in the bladder, slips into a sacculus the symptoms suddenly subside and the stone can no longer be felt by the searcher. Digital rectal examination may sometimes reveal the presence of such calculi. The ridges of a fasciculated bladder may become encrusted with phosphatic deposits and give rise to possible errors in diagnosis in the use of the searcher. When only one sacculus is developed it may become enlarged, even to the size of the bladder, and give rise to the erroneous designation "*double bladder*." Below and in front the longitudinal fibers of the *external layer*, known from its action as the *detrusor urinæ muscle*, pass on each side in front of the prostate to the back of the pubic bones as the *vesicopubic muscle*, while superiorly the longitudinal fibers are continued into the urachus. The *circular fibers of the middle layer* are aggregated near the vesical outlet where they are known as the *internal sphincter* of the bladder, though Henle has shown that their action is to empty the bladder of the last drops of urine, the real internal sphincter being the circular fibers of the upper prostatic urethra.

The entire bladder is *invested by the rectovesical fascia* which is much thicker at its lower part. The *elastic submucous layer* is intimately connected with the mucous membrane which it loosely connects with the muscular layers, except over the trigone, where the two are closely adherent, a fact of importance, for otherwise the trigonal mucous membrane would be prolapsed into and block up the urethral orifice during micturition. As a result of this adhesion the mucous membrane of the trigone is always smooth, while that of the rest of the bladder is thrown into rugæ when the bladder is empty. The laxity of the mucous membrane allows of the great changes of size of the viscus. The mucous membrane is rose colored, but over the trigone it is somewhat paler.

**Blood and Nerve Supply.**—The blood, derived from the *three vesical arteries* and small twigs from the arteries of the neighboring parts (uterine and vaginal in the female), is returned by the veins into the internal iliac vein. When inflamed the mucous membrane is deeply injected and bleeds readily. The *veins form plexuses* around the lower end or base of the bladder, which are connected with those of adjacent parts, especially with those of the prostate in the male, forming the *vesicoprostatic plexus*. Hence in enlargement of the prostate this plexus becomes varicose (*vesical hemorrhoids*), from the pressure of the enlargement upon it. In such cases the varicose veins project into the bladder near its outlet where they are *liable to bleed* spontaneously or from the use of instruments and, by producing a swelling and congestion of the mucous membrane here, they *cause frequent micturition*. The bleeding may temporarily relieve the congestion and the symptoms caused thereby. Bleeding from the bladder usually indicates tumor or stone.

The *lymphatics* of the bladder are not numerous, except perhaps near the outlet, and their existence even has been denied by Sappey. They empty into the internal iliac nodes. Resorption from the bladder contents probably does not occur when the mucous membrane is intact, but only a slight diffusion.

**The nerves** are derived from the *hypogastric plexus, supplying the mucosa*, and the *third and fourth sacral nerves supplying the muscularis*. The mucosa of the greater part of the bladder is only slightly sensitive, as may be observed in the passage of a sound or searcher, that of the trigone and the neighborhood of the outlet is much more sensitive. When the bladder is inflamed its mucosa, especially that near the outlet, is much more sensitive, as seen in cases of cystitis or in stone. In the upright position the stone gravitates to the highly sensitive trigone, and in micturition it is forced against the outlet, causing great pain and perhaps suddenly checking the flow of urine. Sudden distension of the bladder causes acute pain, but it may become gradually distended with only a sense of discomfort.

When the *nerves* supplying the bladder are *paralyzed* from injury or disease of the cord, *distension ensues* from lack of power to empty it, and the consciousness of the bladder being distended is lost. Thus we have *retention of urine*, but in time the outlet is opened up by the pressure and overflow or *incontinence of urine* occurs, the bladder remaining distended. In the child incontinence (usually nocturnal) generally occurs from irritability, not from distension. Retention may also occur from obstruction due to stricture, enlarged prostate, etc., but however it occurs, *long-continued over-distension produces temporary paralysis* by stretching the muscular fibers. Thus the urine flows from the catheter without force and catheterization must be continued for some time. The sudden complete evacuation of all the urine in an over-distended bladder, by removing the pressure on its blood vessels, causes such a relaxation and over-filling of them that oozing of blood occurs into the bladder. Hence the advice not to completely empty at once an over-distended bladder. In cases of repeated or long-continued

over-distension the ureters become distended, even to the size of the small intestine, not by a reflux from the bladder, for the greater the pressure within the bladder the more tightly are their orifices closed, but by an accumulation within the ureters which cannot enter the bladder.

FIG. 86.

Trigone of the bladder with a flap of mucosa dissected up from the greater part of it, showing the mode of termination of the ureter and the prolongation of the bundles of its longitudinal muscle fibers along the boundaries of the trigone. A grooved director leads to post-trigonal pouch. (TESTUT.)

The interior of the bladder presents three orifices, the outlet or *internal urinary meatus*, at the most dependent part of the bladder in the erect position and at the apex of an equilateral triangle, the trigone, whose two other angles are formed by the *orifices of the two ureters*, each one inch (18 to 25 mm.) from the outlet. Connecting the two ureteral orifices and bounding the base of the trigone is an arched elevation (*plica ureterica*), due to a band of muscle fibers continued from the ureters. In chronic cases of obstruction, as in cases due to prostatic hypertrophy, this ridge forms the anterior boundary of the depression known as the *postprostatic pouch* (*fossa retroureterica*). The longitudinal mesial ridge of mucous membrane, the *uvula vesica* (or *uvula of Lieutaud*), passes from the middle of the above ridge to near the outlet, where it is most prominent. It is especially marked in old age and corresponds to the middle portion of the prostate.

The ureters, reaching the bladder  $1\frac{1}{2}$  inches apart, pass so obliquely through its wall for half an inch that their *oblique passage* serves the purpose of a valve, preventing reflux from the bladder and acting more perfectly the fuller the bladder. Under pathological conditions the valvular action may be imperfect, allowing backward flow, and Lewin's experiments on rabbits would indicate that the same may occur under normal conditions when the bladder is not too full.

The female bladder has its *longest diameter transversely* owing to the greater width of the female pelvis and the presence of the uterus and vagina behind it. Owing to the less depth of the symphysis the *outlet is relatively lower*, i. e., horizontally behind the lower end of the symphysis; and, there being no prostate, it is a trifle nearer the symphysis and *very distensible*. This distensibility of the outlet, in connection with the shortness and dilatability of the urethra, enables us to explore the female bladder with the finger, to remove stones and foreign bodies through the urethra, and to more readily examine the interior of the bladder with the cystoscope. For the same reason stone and cystitis are less common and foreign bodies, introduced per urethram, more common than in the male. The *peritoneum does not descend so low* on the posterior surface in the uterovesical pouch, which separates the bladder from the body of the uterus, as in the male in the rectovesical pouch. Below this pouch the *bladder is in contact with* the cervix uteri and the upper half of the vagina. A slight continuation of the subperitoneal connective tissue extends between the bladder and the cervix, thus facilitating their separation in removal of the cervix or uterus, if the operator follows this tissue layer. The close *relation of the bladder and the vagina* explains the frequency of *vesicovaginal fistulae*, which are apt to follow a tear or sloughing of the anterior vaginal wall, the result of difficult labor. The *ureteral orifice* is 3 cm. below the cervix uteri and opposite the middle of the vagina, hence calculi can be felt per vaginam in the lower ends of the ureters, which are also in danger of being injured in operations on the cervix.

The *bladder in the infant* is *pear-shaped*, with the small end above and in front at the urachus, which represents the stalk of the pear. At birth the *outlet* is behind the upper margin of the symphysis and the *bladder is largely in the abdomen* and entirely above the level of the symphysis, only about one half of the organ being below the pelvic brim, as the pelvis is small and occupied mainly by the rectum. Hence in perineal lithotomy in young children the knife must be directed well upward to reach the bladder. The position and relations of the bladder begin to change when the child commences to walk and are about like those of the adult by the age of six. Before this condition is reached the *anterior wall* of the bladder, uncovered by peritoneum, is *in contact with the anterior abdominal wall* and readily accessible to suprapubic operations or puncture. In young male children the *rectovesical fold* extends nearly or quite to the base of the very small prostate, which brings it very close to the vesical outlet, in fact at birth it reaches this level. The *bladder wall* is so *thin* that it is said that a "click" may be elicited through this wall from the pelvic bones in sounding for stones.

**Formation.**—The bladder, female urethra and the prostatic and membranous parts of the male urethra are formed by that portion of the *allantoic vesicle* which lies within the body cavity and extends between the hind gut and the umbilicus. The upper part of this is normally obliterated to form the urachus, the lower part is par-

titioned off from the cloaca, or common opening of the urinary and alimentary tracts, by the growth of a partition which forms the perineum.

**Malformations.**—Faulty growth of this partition may lead to fistulae between the rectum and bladder or urethra. *Extrophy*, or congenital hiatus of the bladder, and *patency of the urachus* have been referred to under Anterior Abdominal Walls (pp. 252 and 259), rectovesical fistula under Rectum (p. 365). These are *congenital conditions*, depending upon errors of development.

**New growths** of the bladder include epithelioma, fibroma, myoma and, in early life, sarcoma. They are especially apt to take on a villous form and to involve, like other pathological processes, the lower part of the bladder, where they may occasionally obstruct the outlet and bleed freely. The contents of the posterior urethra can pass readily into the bladder, those of the anterior urethra only by injection under high pressure. *The bladder may be reached and opened* for exploration, drainage, or the removal of stone, foreign bodies, tumors, etc., by two routes: (1) *perineal* (see Perineum); (2) *suprapubic* (see pp. 254 and 367).

### The Prostate.

The prostate (Figs. 85, 87, 93, 94 and 95) is an elastic, contractile organ of the male generative system which embraces the vesical outlet and encloses the first (prostatic) portion of the urethra. That it belongs to the generative rather than the urinary organs is shown by its small size during childhood, its sudden growth at puberty (together with the testicles, etc.), its atrophy or small size after castration and in eunuchs, and its anatomical relations with the ejaculatory ducts and the prostatic utricle. These facts led to the suggestion, by J. William White, of castration for prostatic hypertrophy.

In size and shape the adult prostate is not unlike a horse chestnut, measuring  $1\frac{1}{4}$  inches from base to apex,  $1\frac{1}{2}$  inches transversely and 1 inch from before backward, and weighing 6 drachms. When the gland is appreciably larger (according to Sir H. Thompson, when it weighs one ounce and measures two inches transversely) **hypertrophy** or **enlargement** of the prostate is said to exist. This may occur occasionally at an earlier age but is so common after the age of fifty-five that it is estimated to occur in 34 per cent. of men over sixty. (Thompson.)

The anatomical effects of enlargement are to lengthen and compress the prostatic urethra, to increase its curvature in many cases and sometimes to produce a lateral curvature (due to the greater enlargement of one side), and to cause the gland to project in the directions of least resistance, backward into the rectum and upward into the bladder, so as to raise the outlet above the most dependent part of the bladder and lead to the formation of the postprostatic pouch. The physiological effects are: (1) increased difficulty of micturition, due to compression of the urethra and obstruction of the vesical outlet by a prominent middle portion and by raising the outlet, and (2) increased frequency of micturition, due to congestion of the lower end of the

bladder from the pressure of the enlargement on the vesicoprostatic plexus.

As a rule the enlargement implicates the prostate pretty uniformly. If the lateral lobes are chiefly involved the gland may attain considerable size without causing serious symptoms, whereas a trifling enlargement of the middle portion or of the glandular portion beneath the floor of the vesical outlet may cause marked obstruction. Occasionally a pedunculated median growth projects into the bladder and obstructs the outlet like a ball valve.

We can clearly distinguish two lateral lobes of the prostate, especially when we look at the posterior surface where they are separated by a shallow furrow. This widens out above into a wedge-shaped furrow, which is continuous with a transverse furrow on the base, in which the ejaculatory ducts enter the prostate. Between this latter furrow and the course of the ejaculatory ducts behind, the urethra in front and the diverging upper ends of the lateral lobes on the sides, lies the "middle portion" or so-called "middle lobe." When normal it is scarcely an anatomical entity but in some cases of prostatic enlargement this part may be principally or exclusively enlarged. In such cases, as it corresponds to the uvula vesicæ, it projects into and obstructs the vesical outlet, occasionally as a pedunculated tumor. The base of the prostate, surrounding the vesical outlet, receives the latter in a funnel-shaped depression somewhat in front of its middle. The prostatic urethra traverses the gland from base to apex a little in front of its middle, rarely it merely grooves the anterior surface or, in other cases, passes more posteriorly.

The position of the prostate is such that its axis from base to apex is nearly vertical in the erect position. The apex, resting upon the deep layer of the triangular ligament, lies  $\frac{1}{2}$  to  $\frac{3}{4}$  inch behind, and a little below the symphysis, and  $1\frac{1}{2}$  to  $1\frac{1}{2}$  inches from the margin of the anus. The posterior surface forms an angle of 45 degrees with the horizon, the anterior is nearly vertical.

Of the relations of the prostate, that of the posterior surface to the anterior aspect of the lower end of the pelvic portion of the rectum is of especial importance for it allows of easy examination through the rectum, the two being separated only by a little loose connective tissue in addition to the capsule of the prostate. It is through the rectum that we can readily distinguish enlargements of the prostate unless there is hypertrophy of the "middle lobe" alone, when nothing can be made out by rectal touch. The lower ends of the seminal vesicles and the ampullæ of the vasa deferentia are in relation with the back of the "middle portion." On the sides it is in relation with the levator ani muscles including their inner and lower borders, and in "lateral prostatectomy" we find that it is this muscle and its ensheathing fasciæ which separate the prostate from the ischiorectal fossa. The base of the prostate is in relation with the bladder for a considerably greater distance behind than in front of the vesical outlet. It is held fixed in position by the parts mentioned in relation with it, viz., bladder,

## PLATE XLIII.

FIG. 87.

Relative position of the bladder, ureter, rectum, prostate, seminal vesicles, vas deferens and their vessels, viewed from the right side. (Joessel.)

rectum, ejaculatory ducts, urethra, levator ani, deep triangular ligament and its capsule, formed of the rectovesical fascia and continuous below with the deep triangular ligament.

The capsule explains in part the course of *prostatic abscess*, i. e., that they seldom extend upward and open into the pelvis, for this course is resisted by the pelvic fascia reflected from the pelvic floor to the base of the prostate to form its capsule, and especially by the puboprostatic ligaments, one of the strongest parts of this fascia. *Prostatic abscesses* extend in the directions of least resistance and accordingly open most often into the urethra, next in order of frequency into the rectum. (See Relations of the Prostate.) Less frequently they open in the perineum, which they reach by running along the side of the rectum, for the dense triangular ligament prevents their passage more anteriorly. When they perforate both the urethra and rectum a *urethrorectal fistula* may result. Prostatic abscess is the result of a *prostatitis*, usually of gonorrhœal origin. Such an inflammation may not go on to abscess formation but stop short of it with enlargement and tenderness of the gland, readily felt by rectum, and with frequent, painful and difficult micturition. The *firmness* of the capsule goes to explain the severe *pain* in acute prostatitis.

Between the capsule and the organ itself is found the **prostatic plexus of veins**, most marked at the sides and in front, receiving at the latter part the dorsal vein of the penis. The plexus connects with the neighboring plexuses, the hemorrhoidal of the rectum, the pudendal and the vesical, especially with the latter with which it forms the vesicoprostatic plexus. *Phleboliths* occur more commonly here than in any other veins. As these veins are cut in lateral lithotomy and other operations they may afford an entrance for septic matter in cases of pyæmia following such operations. These veins empty into the internal iliac vein.

In structure the prostate is a *musculo-glandular* organ. The *glands* are chiefly at the posterior and lateral parts of the organ and open into the floor of the sinuses of the prostatic urethra. They sometimes contain pathological concretions. The anterior part of the organ in general and the anterior commissure in particular contains but few glands. The *muscle tissue* is largely of the unstriped variety but a certain amount of *striped fibers* lie in front of the prostatic urethra and surround the lower part of it. The *unstriped fibers* (1) surround the urethra, forming the true **internal sphincter** of the bladder at the upper end of the urethra, where they are continuous with the muscle of the trigone and the circular fibers of the bladder; (2) they are condensed into a *musculo-fibrous sheath* between which and the fibrous capsule lies the venous plexus, and (3) they form the proper *stroma* of the organ.

In **hypertrophy** of the prostate the enlargement is in some cases more glandular, in others more muscular. Besides senile hypertrophy and enlargement from prostatitis or abscess, the prostate may become enlarged from tuberculosis, carcinoma, myoma or adenoma.

The prostate may be reached for *operation* through the perineum or through the bladder, suprapubically. It is only separated from the ischiorectal fossa by the levator ani muscle and its two investing fasciae, the anal and rectovesical. From below it may be most freely exposed by a curved transverse incision in front of the rectum (Zuckerkandl's incision), or an antero-posterior incision curving around the left side of the rectum (v. Dittel's incision).

**The two ejaculatory ducts** (Fig. 95) are the outlet into the prostatic urethra of the seminal vesicles and the vasa deferentia, by the junction of which they are formed at the base of the prostate,  $\frac{1}{4}$  to  $\frac{1}{3}$  inch behind the vesical outlet. They pass thence downward and forward behind the middle lobe and between it and the lateral lobes of the prostate, and then along the sides of the prostatic utricle to open on either side of the mouth of the latter on the verumontanum, in the floor of the prostatic urethra. They are about  $\frac{3}{4}$  inch long, converge slightly and decrease in size from above downwards from  $\frac{1}{8}$  to  $\frac{1}{25}$  of an inch.

In sagittal *incisions* in the prostate behind the urethra, not exactly median in position, one of these ducts is wounded. This is objectionable, especially in young subjects, as it may result in closure of the duct. An oblique radiating incision, as in lateral lithotomy, is less likely to wound them. *Inflammation* may extend through the duct to the vas deferens and thence to the epididymis from the bruising of the aperture of the duct in the extraction of a stone or a fragment or in the passage of an instrument, or from the extension of an urethritis. This and not metastasis is the usual origin of epididymitis, as is indicated by slight enlargement and tenderness of the vas, though attention is not usually called to it by any marked symptoms. The injection into the prostatic urethra of solutions of nitrate of silver, etc., in cases of derangement of the sexual function is intended to act upon the openings of the ejaculatory ducts.

A peculiar and occasional condition known as "spermatic colic," characterized by sharp pain after sexual intercourse or defecation and sometimes by the absence of ejaculation and the presence of blood in the urine, is due to an obstruction, more or less complete, of the ejaculatory duct by spermatic granules held together in a mucous vehicle. It may be cured by the passage of a sound with or without pressure of the finger in the rectum.

### The Seminal Vesicles.

The two vesiculae seminales (Figs. 85 and 87) are symmetrically placed on the two sides between the base of the bladder and the front of the pelvic portion of the rectum. They extend from the ejaculatory ducts, at the base of the prostate, upward, backward and outward for about two inches, at an angle of  $50^{\circ}$  to  $60^{\circ}$  with the horizon. Their position varies somewhat with the condition of the bladder and follows that of the rectum, for the posterior part of their sheath is composed of that part of the rectovesical fascia which forms the fascial covering of the rectum and thus connects them closely with the rectum. The lower ends of the vesicles are palpable through the rectum above

the base of the prostate, especially if the hand presses the surface about the anus strongly upward and the prostate is not enlarged. The seminal vesicles are more readily palpated when the bladder is full and when they are enlarged or hardened by disease. By the finger in the rectum we can press downward the contents of the vesicles into the prostatic urethra and thence externally. The same result may follow the passage of large hard fecal masses through the rectum, which may cause a nervous man to fancy he has spermatorrhea. The *upper third* of the seminal vesicles is covered behind by the peritoneum of the rectovesical pouch, which separates this portion from the rectum. This pouch sinks somewhat lower in the space between the vesicles.

*Anteriorly* the capsule of the seminal vesicles is connected by loose tissue with the base of the bladder. The vesicles, together with the ampullæ of the vasa deferentia along their mesial borders, lie along the lateral borders of the *trigone* of the bladder and the fossa retroureterica, so that in distension of the bladder the latter fossa projects between the seminal vesicles. The triangular area between the lower ends of the vesicles and ampullæ is the area where the rectum and bladder are closely connected without the intervention of peritoneum (see page 360). The *upper ends* or bases of the vesicles are 6 to 7 cm. apart, they approach the lateral pelvic walls and overlap the lower ends of the *ureters* just before the latter pierce the bladder.

The vesicles are loosely connected with their *capsules* from which they are readily shelled out. When so shelled out we see that their lobulated appearance is due to the *convolutions* of a blind tube, about four or more inches long, and to numerous blind sacculi and lateral branches. The *capsule* is continuous with that of the prostate and with the rectovesical fascia, and contains several scattered muscle fibers. Enclosed within its capsule each vesicle presents an elongated triangular shape, the lower and smaller end of which opens by a free aperture into the lateral wall of the ampulla to form the ejaculatory duct. The seminal vesicles vary much in size not only in different persons but on the two sides of the same person. Cases are also reported where one or both vesicles have been found wanting, the latter condition usually in anorchids.

The vesicles *secrete* an albuminous fluid which usually contains a few spermatozoa which have wandered there by their own motility, for it is now thought improbable that they serve as reservoirs for the semen. The contents of the vesicles add to the bulk of the fluid ejaculated.

The vesicles from their position, about the center of the pelvis, are well protected from *injury*, which rarely affects them. *Inflammation* may extend into the seminal vesicles from the prostate through the ejaculatory ducts, and, if an abscess forms, the relations of the vesicles show that it may break into the bladder, rectum or peritoneal cavity, and that it may involve the vas, the prostate or the ureter. Tuberculosis of the seminal vesicles is not uncommon and forms one of the varieties of genito-urinary tuberculosis. It is usually an extension from neighboring parts.

The seminal vesicles may be *exposed* and *removed* through a curved transverse incision a little in front of the anus (Zuckerkandl's method) or a median incision encircling the anus on one side. The anterior fibers of the levator ani are divided, exposing the prostate, and then the rectum is separated from the bladder, exposing the seminal vesicles.

### The Vas Deferens. (Fig. 87.)

This continuation of the epididymis, or efferent duct of the testis, extends from the globus minor to the ejaculatory duct. In the scrotum it lies behind the testis and internal to the epididymis, thence it extends upward to the external ring as one of the constituents of the **spermatic cord**, behind and internal to the other constituents of the cord. In this position it is readily *felt* and avoided in operations for varicocele, or exposed and divided in the operation of vasectomy, proposed as a substitute for castration in prostatic hypertrophy. It is readily felt as a uniform, firm, round, whipecord-like structure. Its firmness is due to the thickness of its walls as compared with the size of the lumen. When affected by tubercular disease it is characteristically nodular. In cases of *inversion* of the testis its position is reversed, lying in front of the testis and the other elements of the spermatic cord.

At the *external abdominal ring* it lies behind and internal to the neck of the sac of an oblique inguinal *hernia* and external to that of a direct inguinal hernia. It may become adherent to the coverings of a hernia, especially in cases of long standing. After entering the *abdomen* through the internal ring it soon diverges from the spermatic vessels and, looping above the arch of the deep epigastric artery, *enters the pelvis* near the iliopubic eminence. It then runs backward and downward on the lateral pelvic wall, and thence onto the postero-lateral aspect of the *bladder*. In this part of its course it *crosses* the external iliac vein, obliterated hypogastric artery and obturator vessels and nerve.

On the *bladder* it lies on the vesical side of the obliterated hypogastric artery and the lower end of the ureter, separated from the latter by a layer of perivesical fat one half inch thick. After crossing over the ureter it bends down on its mesial side onto the base of the bladder, where it lies between it and the rectum, adjacent and internal to the *vesiculae seminales*. Here it becomes enlarged and somewhat sacculated as the *ampulla* whose relations are similar to those of the seminal vesicles already described (q. v.). Near the base of the prostate, and the inferior angle of the triangular area where the bladder and rectum are in contact, it narrows down and is joined by the *vesiculae seminales* to form the *ejaculatory duct*.

The entire *pelvic portion* of the *vas*; except that at the base of the bladder, is *subperitoneal* and quite closely attached to the peritoneum, so that when the latter is raised it tends to follow it.

The *infection* from a *urethritis* may extend along the *vas* to the *epididymis*, giving rise to *epididymitis*. In such cases the *vas* becomes

swollen to the size of a lead pencil and tender; but the inflammation of the vas speedily subsides and generally leaves no trace. The ampulla of the vas may be palpated, exposed and operated upon in the same way as the seminal vesicles.

The *artery* of the vas deferens, derived either from the superior or one of the inferior vesical arteries, forms an important *anastomosis* with the *spermatic* artery at the lower end of the epididymis, which is sufficient to nourish the testis when the *spermatic* artery is ligated in the operation for varicocele.

## THE FEMALE PELVIC GENITAL ORGANS.

### The Uterus.

The uterus lies within the pelvis between the bladder and the rectum and, together with its lateral or broad ligaments, divides the pelvic cavity into an anterior or uterovesical and a posterior or uterorectal compartment. Its size and shape vary with age and many physiological and pathological conditions. In *shape* it is pyriform and flattened from before backward, except when affected by unsymmetrical new growths like fibromyomata, cancer, etc. The fundus is on a level with the uterine ends of the Fallopian tubes in nulliparae and about 1 cm. above in multiparae. In the *infant* and the child before puberty it is relatively small in *size*, the *cervix* is larger than the body, and the *intravaginal* segment of the *cervix* is relatively large. In the *uterus* of a young adult *virgin* the length is about equally divided between the *cervix* and the *body*. In the *nulliparous* married woman the *body* becomes somewhat larger than the *cervical* portion. When completely *involtuted* after childbirth the *uterus* is always somewhat larger than before conception and the length of the *body* is twice that of the *cervix*. In *old age* the entire organ atrophies and this process begins after functional activity ceases at the menopause. In the *nulliparous* adult the *length* is about  $2\frac{1}{2}$  inches, the greatest *breadth*  $1\frac{1}{2}$  inches; after childbirth the dimensions are about one fifth greater.

The *weight* in nulliparae is about an ounce, in multiparae an ounce and a half, in old age it may be as little as one to two drachms, while at full term it may vary between twenty-two and forty-six ounces. The weight is somewhat increased during menstruation. Increase of weight may be due to pregnancy, inflammation, new growths, etc., and may cause various malpositions.

**Position.**—The uterus of the infant and *child* projects above the pelvic brim and lies almost wholly in the abdomen, compressed between the bladder and rectum and without flexion as a rule. *Before puberty* it comes to lie entirely below the pelvic brim, but above a horizontal plane passing through the upper end of the symphysis, and remains so unless enlarged by pregnancy or by pathological processes.

The uterus, especially the *body*, is very *movable* so that its *axis* is without doubt subject to considerable variation within normal limits. According to some it ordinarily coincides with the long axis of the

body, but it may incline forward as much as  $15^{\circ}$  or  $20^{\circ}$  when the bladder is empty, and the full rectum pushes it forward and deflects it slightly to the right. Others give its axis as in line with the axis of the pelvic inlet, and others still (Joessel, Waldeyer) as *anteflexed* from  $70^{\circ}$  to  $100^{\circ}$ , and also *anteverted*. According to the latter author the *external os* is on a *level* with the upper end of the *symphysis*, in a transverse vertical plane passing through the spines of the ischium, and the axis of the *cervix* is in line with that of the pelvis at this point. The condition of the neighboring intestinal coils may also affect its position. As the uterine axis forms an angle with that of the *vagina* the lower end of the *cervix*, including the anterior and posterior lips and the *external os*, abut against the posterior *vaginal wall*.

**Fixation.**—The broad or lateral ligaments fasten both the body and *cervix* to the lateral walls and floor of the pelvis. The body is also supported by the round ligaments attached to its cornua and so directed as to hinder its posterior or lateral displacement and to some extent its downward prolapse. The other ligaments of the uterus, both true (uterosacral) and false (anterior and posterior) steady the *cervix* fore and aft. In addition the *cervix* is *fixed* by its attachment to the bladder and *vagina* so that it is the most fixed part of the uterus. When the uterus becomes enlarged from *pregnancy* or otherwise the ligaments stretch or lengthen to accommodate themselves to the new conditions. During involution of the uterus after childbirth the ligaments again contract and shorten, but if the uterus remains subinvolved or the patient gets up too soon, and especially if she strains herself by work before the balance between the uterus and its ligaments is reestablished, there is danger of uterine displacement, as it is not properly supported.

**Relations.**—As the *rectum* lies behind it we can examine the uterus, to determine its size and position, by palpation through the *rectum* almost if not quite as well as through the *vagina*, especially if there is retroflexion or retroversion.

Between the uterine body, the supravaginal portion of the *cervix* and the upper part of the *vagina* in front and the *rectum* behind lies the rectouterine pouch of peritoneum (*pouch or cul de sac of Douglas*), bounded laterally by the posterior false ligaments of the uterus, enclosing the uterosacral ligaments. Douglas' pouch normally contains coils of small intestine and perhaps part of the sigmoid loop. It is readily examined by the finger per rectum or per vaginam, or opened into through the posterior vaginal fornix, and it is the seat of retrouterine hematocele. The peritoneum is reflected from the front of the isthmus onto the *bladder* to form the *uterovesical pouch*. This contains coils of intestine and is much shallower than the pouch of Douglas. The subperitoneal connective tissue continues down below this reflection of peritoneum and separates the *cervix* from the *bladder*, allowing the separation of the two along this plane in hysterectomy. This layer is continuous with that found at the sides of the *cervix*, between the layers of the broad ligaments, and with a more scanty amount beneath

## PLATE XLIV.

FIG. 88.

The female pelvis and pelvic viscera from above, the uterus and adnexa being drawn forward. (Testut.)

the peritoneum covering the back of the supravaginal portion of the cervix. The *cervix* is thus seen to be enclosed in a layer of *loose connective tissue* of varying thickness, continuous with the subperitoneal connective tissue. This facilitates the amputation of the cervix without opening the peritoneal cavity (*i. e.*, extraperitoneal).

From the above we see the relation of the uterus to the peritoneum which covers the anterior and posterior surfaces and the upper end of the body, and the supravaginal portion of the posterior part of the cervix. It is reflected from the sides of the body and cervix to form the broad ligaments.

New growths, like carcinoma of the uterus, may extend onto the rectum or bladder and vice versa, and the *ureters*, on account of their close relations to the cervix, may become occluded from the extension of a carcinoma of the latter, and uræmia result.

**The Cervix.**—Of the *three zones* (Fig. 91) into which the cylindrical cervix is divided the lower or *intravaginal zone* projects into the upper part of the vagina at such an angle that its lower end abuts against the posterior vaginal wall. This lower end contains the *external os*, or lower opening of the uterine canal, bounded by a lower *anterior lip*, short and thick, and a *posterior lip* which is longer than the anterior by reason of the greater height of the posterior vaginal fornix. The *orifice*, a transverse fissure a quarter of an inch broad in the virgin, becomes irregular after childbirth owing to the notching of its lips, so that by palpation of the *os* we can say whether a woman has borne children. This intravaginal portion of the cervix can be *seen* through the speculum or *examined* by the finger in the vagina, and is more exposed to lesions of all sorts than other parts of the cervix, especially to "erosions" and cancerous ulcerations. The first part that we see or feel on examination is the anterior lip.

The *cervix* may become *hypertrophied* so as to be *elongated* and project downward into the vagina unusually far. This may resemble a prolapse, but if we try to push it up, usually an easy matter in prolapse, resistance and pain are at once met with from the tension of its connections. This *elongation* may affect either the intra- or supravaginal portion of the cervix. In the former case the vaginal fornices are deepened, in the latter they are not. Such a cervix may even interfere with coitus, and a conical, pointed cervix is unfavorable to *conception* and may be a cause of *sterility*. Another cause of sterility as well as of dysmenorrhœa is furnished by an *atresia* or narrowing of the *os externum*, by no means rare. The cervix may be enormously *enlarged* from chronic disease. During *pregnancy* it becomes broad and soft and is drawn up from the cavity of the vagina, the *external os* being occluded by a plug of mucus. The intravaginal portion, relatively large and prominent in female children, may nearly completely disappear in *old women*, and sometimes in younger multiparæ. It possesses so little *sensation* that we can insert sharp hooks to pull it down and make all manner of applications to it without producing much if any pain.

The **zone of vaginal attachment**, about one fifth inch deep, is obliquely placed, extending higher behind than in front, thus making the posterior lip longer and the posterior vaginal fornix deeper.

The **supravaginal zone** represents about half of the cervix behind and two thirds in front. It is connected, as we have seen above, with the *bladder* anteriorly, while posteriorly it is covered by peritoneum and enters into the anterior wall of *Douglas' pouch*. Perhaps the most important relations of the cervix are found at its sides which are connected with the *broad ligaments*, in which at this level lie the uterine vessels and the ureter. The *uterine artery* passes nearly horizontally inward in the base of the broad ligament to the supravaginal portion of the cervix, accompanied by the large uterine veins, arranged in a plexiform manner.

One of the most important topographical points in the female pelvis is the **crossing of the uterine artery in front of the ureter**. This occurs on a level with the intravaginal portion of the cervix and about 2 cm. (four fifths of an inch) *from the cervix*. The ureter passes *through the plexus* of the uterine veins. The fact of the crossing is important for it occurs close to where we tie or clamp the uterine vessels in removing the uterus or cervix. Hence there is danger of *wounding the ureter*, a danger which is real for it has occurred in many reported cases. After crossing behind the uterine arteries the two *ureters*, converging slightly, incline somewhat forward so as to reach the front of the sides and then the anterior wall of the vagina.

**Displacements.**—As we have seen (Fixation, page 380) the *cervix* is the *most fixed* part of the uterus, while the ligaments holding the body allow it more freedom of motion. The slightly constricted part (*isthmus*), where the more fixed cervix joins the heavier and more movable body, is an exposed and *weak point* where ante- and retroflexions occur, the body of the uterus bending and the cervix retaining its proper position. In **anteflexion** the body is bent forward onto the bladder and we can palpate it by combined vaginal and abdominal palpation, while in **retroflexion** the body occupies *Douglas' pouch* and presses upon the rectum, through which or the vagina it may be readily palpated. A certain degree of anteflexion is not pathological but probably normal.

If the uterus is ante- or retroverted it seesaws on the *isthmus* as a transverse *axis* so that if the body moves in one direction the cervix is forced in the opposite direction. Thus in **anteversion** the body lies upon the bladder while the vaginal portion of the cervix tilts up and back into the posterior vaginal fornix; in **retroversion** the cervix, tilted forward, presses against the bladder while the body of the uterus presses against the rectum. In either of these cases it may be difficult to make the external os present at the end of a speculum.

Any of these malpositions may tend to *prevent conception*, by reason of the position of the os or the obstruction due to the sharply bent canal. Anteversion is said to be more common among childless women, retroversion among women who have borne children, especially

if after labor they have been bandaged too tightly and too long in the supine position.

As the *round ligaments* prevent backward displacement of the uterus their *relaxation* allows of retroversion, and their *shortening* produces anteversion, which may also be caused by the retraction of the *utero-sacral ligaments*, by pulling the cervix backward and thus tilting the body forward. In anteversion or anteflexion the body of the uterus may so press upon the *bladder* as to cause much *irritability*. In retroversion the cervix presses upon the bladder near its outlet so as to cause more irritability of the bladder than the pressure of the anteflexed or anteverted uterus upon its upper part. In the same manner the body in retroversion or retroflexion and the cervix in anteversion may so press upon the *rectum* as to cause rectal *tenesmus* and difficult and painful defecation and thereby induce *constipation*.

The uterus displaced in any of the above ways may regain its normal position unless adhesions occur and fasten it to the viscera against which it presses, whereby the symptoms due to pressure become chronic. Either form of flexion may cause *dysmenorrhœa* by obstructing the escape of the menstrual flow. When the supporting ligaments are relaxed and this condition is combined with a weakening of the support of the perineum, following its rupture, and an abnormally heavy uterus, the latter may sink or become *prolapsed* so as to present at the vulva or even to lie partly or wholly outside the vulva. A much rarer condition, and one more difficult to treat, is where the uterus is *inverted* or turned inside out, which may be due to the traction of a polypoid submucous fibroid.

The small **cavity** of the uterus is a mere fissure. The cavity of the body is triangular in shape with an opening at each angle, the Fallopian tubes above and the narrow **internal os** below. The latter opening is at the upper end of the fusiform cervical canal which ends below in a transverse fissure, the **external os**. The narrowness of the **os internum** may be such as to be an obstacle to the menstrual flow and a cause of dysmenorrhœa. In old age it becomes still more contracted and even closed. The **cervical canal** may be gradually yet fairly quickly dilated so as to allow inspection and digital examination of the uterus and even the enucleation of large tumors. The **mucous membrane** of the cervical canal secretes a viscid alkaline mucus and pathologically its mucous glands are liable to become vesicular, when they are sometimes known as *ovula Nabothi*. The motion of the cilia of the uterine mucosa is downward toward the **os externum**. The length of the uterine cavity averages about two inches in nulliparæ and  $2\frac{1}{4}$  to  $2\frac{1}{2}$  inches in multiparæ. We can determine the length by the uterine sound.

As there is, strictly speaking, no cavity, the bulk of the uterus is made up of its **thick wall**. Apart from its remarkably thick **mucous membrane**, which is thickened and then partly cast off at the monthly periods and becomes the *decidua* during gestation, this thick wall consists principally of unstriped **muscle fibers**. This tissue, arranged in

three imperfect layers, is remarkable for its hypertrophy and new growth during pregnancy, and it is largely by its contraction that the foetus is expelled. The muscle tissue of the uterus is continuous with that of the utero-sacral, round, utero-ovarian, and broad ligaments, and that of the Fallopian tubes, vagina and bladder.

In this tissue in any part of the uterus, but more often in the body, develop the common *fibroids*, myomata or fibromyomata, as they are variously called. These may be single or more often multiple and may attain a very large size; one of one hundred and forty pounds has been recorded, but as a rule they do not attain the size of the largest ovarian tumors. In their evolution they often acquire a partial or a complete *capsule* and may protrude on the surface (*subperitoneal variety*), or into the cavity (*submucous variety*), or they may remain well enclosed in the walls (*interstitial variety*). They occur during menstrual activity, they tend to degenerate after the menopause and sometimes become involuted with the rest of the uterus after parturition. They are particularly common among negroes. The *submucous variety* is apt to cause severe *bleeding* and hence should be removed early. The *subserous variety* is liable to adhesions from local peritonitis. They may prevent conception, cause miscarriage or complicate parturition, according to their size and situation.

The uterus, enlarged from pregnancy or other cause, may press upon the iliac vein, causing hemorrhoids or varicose veins of the legs; on the lumbar or sacral nerves, causing neuralgia and cramps; or on the renal veins or kidneys, causing albuminuria, etc.

Owing to its small size, its great motility and the protection afforded by the pelvis the unimpregnated uterus is rarely *wounded*. The *pregnant uterus* may be *ruptured* by violence or by its own contraction during labor, especially if the passage of the foetus is obstructed. The rupture is usually near the junction of the cervix with the body.

**Vessels.**—The uterus is supplied by the *uterine arteries* from the internal iliacs and the *ovarian* from the abdominal aorta. The *uterine artery* of either side passing horizontally inward in the base of the broad ligament *crosses in front of the ureter* (see p. 382), and reaches the side of the cervix whence it runs up along the side of the uterus, between the folds of the broad ligament. At the cornu or angle it *anastomoses* freely with the ovarian artery. In young individuals the artery lies  $\frac{1}{2}$ –1 cm. from the uterus and still further removed from the cervix and the lower part of the body. After repeated pregnancies it comes to lie nearer the uterus and becomes more tortuous so that in operations it is more difficult to separate the artery from the uterus.

At the uterine end of the round ligament the small *funicular artery*, accompanying the round ligament, anastomoses with the uterine and ovarian arteries. Numerous transverse branches from the uterine arteries supply the uterus and anastomose across the median line. Owing to this fact and the free anastomosis with the ovarian artery, a ligature may be placed around the uterus without affecting the circulation above or below.

By a lateral *incision* into the upper end of the *vagina*, opening into the base of the broad ligaments, the *uterine arteries* may be pulled down and *tied*, the relation of the artery to the ureter being carefully borne in mind, as it should be also in securing and dividing the artery in *hysterectomy*. The *veins* form *large plexuses* and accompany the corresponding arteries.

The *lymphatics* from the *cervix* accompany the uterine veins and enter the *pelvic nodes*, beneath the bifurcation of the *iliac artery*, those from the body accompany the ovarian veins and enter the *lumbar nodes*.

**Development.**—The uterus and vagina are formed by the fusion of the lower ends of the two *ducts of Müller*, the two ununited upper ends of which form the Fallopian tubes. The *bicorned* and *double uterus* are due to the failures of this fusion in whole or in part, and they may be associated with a partial or complete septum dividing the vagina. Pregnancy as well as many of the pathological conditions may be confined to one half or one cornu of a malformed uterus.

The *uterus* is reached for operation through a median *cæliotomy* or through the *vagina*. In its removal (*hysterectomy*) its connections with the broad ligaments, *vagina* and *bladder* are the principal things to be divided or separated. Remember that its *two arteries reach it through the broad ligament*, the ovarian at its cornu, the uterine opposite the *cervix*. We repeat again that the relation of the ureters to the *cervix* and the uterine vessels must be borne in mind.

### The Ovary.

The ovary is a paired organ, shaped like a broad almond whose *length* is  $1\frac{1}{2}$  inches, *breadth*  $\frac{3}{4}$  inch, *thickness*  $\frac{1}{2}$  inch. Its *weight* is about 100 grains in the adult, the right being usually a little larger. Before puberty it is small, it enlarges at puberty, and after the menopause atrophies very much.

**Position.**—We may describe a *typical position* of the ovary remembering that, being a *movable body*, it may temporarily occupy other positions without causing any disturbance. The latter positions may more readily change into *abnormal positions* which do cause functional disturbances.

When the other pelvic organs are normal and there have not been repeated pregnancies, the *typical position* of the ovary in the upright posture is with its *long axis* vertical, its *attached border* in front and slightly external, its *free border* behind and slightly internal, toward the rectum, its *lateral surface* against the lateral pelvic wall in the *fossa ovarica*, and its *mesial surface* looking into the pelvis.

The *fossa ovarica*, or the depression on the inner surface of the internal obturator muscle in which the ovary lies, varies much in depth and is *bounded* above and in front by the superior vesical artery, behind by the ureter and uterine artery, below and in front by the lateral attachment of the broad ligament. Lodged in this fossa the *lateral surface* of the ovary is not visible and the attached border, upper end, and a variable amount of the free border and mesial surface are

covered by the Fallopian tube, so that *but little* of the ovary may be visible on inspecting the pelvis.

The two ovaries are *seldom entirely symmetrical* in position, one being higher or more anterior than the other and, if the uterus is deflected to one side (according to His, to the left side in the proportion of three to two), the ovary on the opposite side is more exposed by the tube being somewhat drawn away from it. In the supine position the ovary lies with its long axis horizontal. The changing relations of the contiguous viscera also probably affect its position.

The ovary may be *displaced* into Douglas' sac or even into the utero-vesical pouch; it may be found, especially in childhood, in an inguinal or femoral *hernia*, where it is liable to strangulation, and it may become fixed in its abnormal position by adhesions. *In pregnancy* the position of the ovary is normally altered. *When enlarged* the ovaries may be *felt* through the vagina, or even better through the rectum. Their *position* is indicated *on the surface* by a point about two inches internal to the anterior superior iliac spine or in a *sagittal plane* midway between the latter spine and the symphysis. A *frontal plane* at the promontory of the sacrum touches or lies just behind the ovaries. The position of the ovary corresponds to the middle of the upper margin of the acetabulum.

The ovary is *held loosely in position* by the attachment of the tuboovarian ligament (*fimbria ovarica*) to its upper end and of the uteroovarian ligament to its lower end, and by being contained within the posterior fold of the broad ligament from which it projects backward so as to be connected with it only along the attached margin. The *ligamentum infundibulo-pelvicum*, a fold of the broad ligament containing the ovarian vessels, passes from the side of the pelvis, above and in front of the ovary, to its attached border where the vessels enter the hilum. This "ligament" helps to *support* the ovary and forms part of the *pedicle* in removal of the ovary or ovarian tumors.

Of the relations of the ovary we have named the most important, the Fallopian tube and the ureter. The ureter, with the uterine artery in front of it, lies behind the ovary. External to the ovary, in the fossa ovarica, are the obturator vessels and nerve. Internal to the ovary, in addition to the tube, are coils of intestine.

**Structure.**—The ovary receives from the posterior layer of the broad ligament an external covering, which differs from the serous membrane of the latter in being covered by *columnar epithelium*. Many of the ovarian *cysts* take origin in this epithelium. The surface is smooth before puberty and more and more scarred during menstrual activity. The *scars* represent where ovisacs have ruptured and the larger ones in multiparae the position of a true corpus luteum which forms when pregnancy occurs. Slight extravasation of blood follows the rupture of an ovisac (or Graafian follicle) but when a vessel of unusual size is ruptured, or possibly when the ovary is unduly congested, a sudden copious bleeding may occur and the blood collect in Douglas' pouch as

PLATE XLV.

FIG. 89.

(Gerrish, after Testut.)

a *pelvic hæmatocele*, which we can then feel as a doughy tumor by vaginal or rectal examination.

The so-called *tunica albuginea* is a thin layer and is merely a condensation of the ovarian stroma. Within it lies the cortex containing numberless *Graafian follicles* (*ovisacs*) in various stages of development and the remains of some that have burst at the menstrual periods. Some ovarian tumors (cystic) are due to a collection of fluid in a dilated Graafian follicle (unilocular) or follicles (multilocular). The ovisacs, as they ripen, enlarge and approach the surface, where they appear as large rounded projections when ready to rupture and set free the ovum.

The ovary may also be affected by *malignant new growths* and by *dermoid cysts*, the latter due to an island of epiblast abnormally included in the mesoblastic ovarian tissue. **Ovarian tumors**, if one side alone is involved, are at first unilateral in position, displacing the body of the uterus to the opposite side, the cervix usually to the same side. Later they ascend into the abdomen, displacing the intestine upward so as to cause dullness on percussion, in distinction to the tympanitic note we obtain in ascites from the bowel floating above or in front of the fluid.

*The vessels* enter or emerge from the ovary at the hilum, near which the ovarian veins form a large plexus in the broad ligament (pampiniform plexus).

**Development.**—The ovary, developed in the lumbar region like the testis, is *pulled down* into the pelvis in a similar manner by the *inguinal ligament* of the primitive kidney. This ligament, attached to the uterus and the inguinal region, *remains* as the *uteroovarian ligament* between the ovary and the uterus, and the *round ligament* between the uterus and the inguinal region. In *hernia* of the ovary the fibromuscular uteroovarian ligament draws the uterus forward and to the side of the hernia, a fact that may be useful in diagnosis.

The upper series of Wolffian tubules may persist as a small pedunculated cystic sac, the *hydatid of Morgagni* (*appendix vesiculosus*), attached to the part of the broad ligament forming the free border of the mesosalpinx and adherent to the fimbria ovarica or one of the other fimbriæ of the tube. The *parovarium* (*organ of Rosenmüller*) is the atrophied remains of the middle series of the Wolffian tubules, which in the male form the epididymis. This *lies* above the ovary in the mesosalpinx and consists of several vertical tubes joining at right angles a horizontal tube, a segment of the Wolffian duct, which lies above them. The Wolffian duct disappears elsewhere as a rule, but may occasionally persist as a small canal in the broad ligament close to the uterus, the *duct of Gärtnér*, which is lost in the vaginal wall or may open near the urinary meatus. In these foetal structures, especially the parovarium, develop the majority of the unilocular cysts of the broad ligament (*parovarian cysts*). These generally contain a clear fluid and may often be cured by simple puncture.

**The Fallopian Tubes (*Oviducts*).**

These *trumpet-shaped* tubes, about  $4\frac{1}{2}$  inches long, are structurally continuous with the uterus at its superior angles from which they pass outward to the sides of the pelvis, where they are closely related and connected with the ovaries. They lie between the two layers of the broad ligaments, along their upper free margins, so that the serous membrane covers three fourths of their circumference and, being reflected off inferiorly, forms the *mesosalpinx*. The lower fourth of their circumference is in contact with the subperitoneal tissue between the layers of the broad ligaments. Thus a *tubal pregnancy* or a fluid collection in the tube (*hydro- or pyosalpinx*) when it ruptures may burst into the peritoneal cavity, a dangerous course, or between the layers of the broad ligament. The tubes lie between and slightly above the round ligament in front and the uteroovarian ligament behind.

**Course and Size.**—At the outset it must be remembered that the tube, lying in the free margin of the broad ligament and connected with two movable viscera, the uterus and ovary, must of itself be *freely movable* and thus affected in its position by the conditions of the neighboring viscera. The *narrow straight* inner portion, or *isthmus* (3–6 cm. long), passes *horizontally* outward and slightly backward from each superior angle of the uterus to the uterine or lower end of the ovary at the side of the pelvis. Thence the *curved and dilated* portion, or *ampulla* (7–9 cm. long), bends sharply upward along the mesial aspect of the attached margin of the ovary to its upper or tubal end, over which it bends backward and then downward along the free border and the mesial surface, upon which rests the *funnel-shaped fimbriated extremity*, fringed by a circle or circles of *diverging fimbriae*  $\frac{2}{5}$  to  $\frac{3}{5}$  inch long. Thus the ovary is more or less hidden (see Ovary, page 386). One fimbria longer than the rest (1– $1\frac{1}{2}$  inches) and attached to the upper end of the ovary (*fimbria ovarica*) constitutes the tuboovarian ligament.

The Fallopian tube forms a *passage way* between the *uterine cavity* (and thus the surface of the body) and the *peritoneal cavity*, whereby the ovum, when it escapes into the latter by the rupture of the ovisac, may reach the uterus. Hence also through this passage way uterine or vaginal douches and microorganisms may reach the peritoneal cavity and cause pelvic and perhaps general peritonitis.

The *fimbriae* of the funnel-shaped outer end of the ampulla of the tube normally so embrace the ovary that they conduct the ovum into the abdominal opening of the tube. When from inflammation these *fimbriae* become adherent together, or to neighboring parts, and close the opening on both sides the ova cannot escape out of the abdominal cavity and *sterility* results. Again, in rare instances when the adaptation of the *fimbriae* is imperfect, an ovum, fecundated by spermatozoa which have passed through the tube, may drop back and develop in the peritoneal cavity as one form of extra-uterine pregnancy.

The *mucous membrane* which lines the tube is arranged in longitudinal folds and lined by a *ciliated epithelium* whose movement is

toward the uterus, thus favoring the passage of the ovum. When from inflammation extending from the uterus, perhaps of gonorrhœal origin, the tube has lost its epithelium the descent of the ovum is hindered and the ascent of spermatozoa is not, thus favoring the occurrence of extra-uterine pregnancy. The lumen of the tube varies, being about 1 mm. at the uterine aperture,  $\frac{1}{8}$  inch in the isthmus,  $\frac{1}{3}$  inch in the ampulla, and  $\frac{1}{12}$  to  $\frac{1}{8}$  inch at the abdominal aperture. Ciliated epithelium extends along the inner surface of the fimbriæ and gradually merges into the endothelium of the peritoneum on their outer surface. The fimbriated extremities furnish the only instance where serous and mucous membranes adjoin one another.

As the result of inflammation the tube may be closed, especially at its narrow points, the two extremities, so that the products of inflammation are pent up within the tube, which becomes distended to the size of the intestine (*hydro- or pyosalpinx*, pus tube). In such cases also the peritoneum on its surface is apt to contract adhesions to neighboring parts. The closure of the lumen of the tubes also causes sterility.

A tube enlarged by tubal pregnancy or from hydro- or pyosalpingitis may be felt by vaginal or rectal examination. They may be reached for operation (1) by the vaginal route, (a) laterally between the layers of the broad ligament, and therefore extra-peritoneally, (b) posteriorly through Douglas' pouch, as in vaginal hysterectomy; (2) through an abdominal incision.

It should be remembered in operations that the fimbriated extremity may be in close relation with the ureter, a matter of importance if adhesions exist.

The tubal blood supply is from a branch of the ovarian artery running along its lower border in the broad ligament which forms its mesosalpinx.

In their development the Fallopian tubes represent the upper extremities or ununited parts of the ducts of Müller; hence morphologically as well as structurally they are continuous with the cornua of the uterus.

### The Broad Ligaments.

These ligaments, also called lateral ligaments from their position on either side of the uterus, form as it were a common mesentery for the uterus and its adnexa, especially the Fallopian tubes. They consist essentially of the two layers of peritoneum which, after covering the anterior and posterior surfaces of the uterus as described (p. 381), are reflected from the sides of the latter to the sides and floor of the pelvis, where they become continuous with the parietal peritoneum.

In addition to the Fallopian tube, ovary, round ligament and foetal relies, the broad ligament of each side contains between its folds, the utero-ovarian ligament, the uterine, ovarian, and funicular vessels, the corresponding lymphatics, the uterine plexus of nerves, unstriped muscle tissue continuous with the uterus mesially, and loose adipose cellular tissue continuous with the subperitoneal tissue of the pelvis. In this tissue at the base of the ligament lies the ureter in relation with the uterine ves-

sels (see p. 382). *Inflammation* of this tissue (*parametritis*, if near the sides of the uterus) is the commonest form of *pelvic cellulitis* in women, and often results in *abscess*. It may spread from an inflammation of the small amount of similar tissue separating the muscular and peritoneal coats of the uterus (*perimetritis*) and it may extend to the similar tissue beneath the parietal peritoneum of the pelvis, or pass over the pelvic brim into the iliac fossa where it often points just above Poupart's ligament (see p. 275).

The *muscular tissue* ensheathes the vessels and is of special importance in serving as a *support* to the uterus and helping to keep it in place. When the uterus enlarges during pregnancy it fills the space between the folds of the broad ligaments so that the latter nearly disappear, to reappear with the involution of the uterus. Hence for a time *after parturition* they are *lax* and offer but feeble resistance to uterine displacements, a reason for not allowing a woman to get up too soon after confinement.

Each broad ligament represents a *quadrilateral plate* which, with the uterus, divides the pelvis into an anterior (uterovesical) and a posterior (uterorectal) fossa. The *inner or mesial border* of the broad ligament represents its attachment to the sides of the uterus and the upper end of the vagina. In this border the uterine vessels pass up along the sides of the uterus. As the posterior fold passes onto the posterior surface of the upper end of the vagina we can understand how an incision in the lateral wall of this part of the vagina will open into the space between the two layers of the ligament at its base, and how we can palpate through the vagina any tumor or swelling situated here. The *base or lower border* of the broad ligaments rests upon the floor of the pelvis, formed by the levator ani and covered by the rectovesical fascia. The abundant areolar tissue here gives passage to the uterine vessels and nerves and the ureter, which pass from behind and externally forward and inward. Here, as well as along its lateral border, its layers become continuous with the parietal peritoneum of the pelvis. Owing to the slant of the pelvic cavity the *anterior layer* is reflected at a higher level than the *posterior*, so that the latter is deeper or longer than the former. It is also more important on account of its direct relation with the ovary and the fimbriated extremity of the tube.

Its *lateral borders* transmit the ovarian vessels and the round ligaments and meet the sides of the pelvis, lined by the obturator internus muscle and fascia. The two layers are continuous along the *free upper border* of the broad ligament which *contains* the Fallopian tube, so that the *upper part* of the ligament forms the *mesentery* of the tube (*mesosalpinx*). But the tube does not extend to the lateral limits of the broad ligament. The *outer part* of the free upper margin of the ligament, beyond the fimbriated extremity of the tube, is at a lower level than the mesial portion (*mesosalpinx*) and *contains* the *ovarian vessels* as they pass from the sides of the pelvis to the ovary. It presents a concave rounded margin and is called the *infundibulo-pelvic ligament*, since it extends

between the infundibulum (fimbriated extremity of the tube) and the side of the pelvis. Together with a portion of the broad ligament, the Fallopian tube and the utero-ovarian ligament it constitutes the *pedicle of an ovarian tumor*.

The upper part of the broad ligament which forms the *mesosalpinx* is *thin*, translucent, devoid of muscular tissue and *contains* the foetal relictus and the tubo-ovarian vessels. Projecting from and attached to the *posterior layer* is the ovary. More mesially the *recto-uterine or posterior ligaments* of the uterus are continuous with this same layer. Between the folds of the broad ligament unilocular *cystic tumors* (usually originating from foetal relictus), haematocele, abscess and tumors are found, of which the cystic tumors are perhaps the most common. These may all be palpated through the vagina and reached for operation by means of a vaginal or abdominal incision. Unlike many ovarian tumors they are commonly sessile and rarely, if ever, pedunculated. We are accustomed to think of the broad ligaments as vertical, and as such to describe them, but when we consider the normal anteflexed position of the uterus we find that the greater part, except the base, of the uterine end of the ligament is more horizontal than vertical.

### The Round Ligaments.

These two rounded cords of unstriped muscle, fibrous and elastic tissue, about five inches in *length*, commence at the upper angles of the uterus just below and in front of the Fallopian tubes, where they are continuous with the superficial uterine fibers. Each *passes* at first downward and outward toward the base of the broad ligament; then nearly horizontally outward near the base of the ligament and beneath its anterior layer, in front of the ureter and the uterine vessels; thence upward, outward and forward over the pelvic brim and the lower end of the iliac fossa to the internal abdominal ring. In the latter part of its course it *corresponds* to that of the *vas deferens* and crosses, like the latter, the obturator and external iliac vessels and the unobliterated portion of the hypogastric artery (*i. e.*, superior vesical artery), and finally loops around the outer side of the curve of the deep epigastric artery to enter the inguinal canal. In this part of its course also it not infrequently projects so far forward as to form a kind of short mesentery. In passing through the inguinal canal it receives a covering from the layers of the abdominal wall like the spermatic cord, but the striped fibers derived from the cremaster are mostly attached to the pillars of the ring and the pubic spine. It may be accompanied by a process of peritoneum, the *canal of Nuck*, which corresponds to the *processus vaginalis* in the male and occurs as a sac-like pouch above and in front of the round ligament, not as a hollow tube around it, as is sometimes described. This serous pouch is *constant* in the foetus, occurs in children in twenty per cent. of cases (Zucker-kandl), and in isolated cases may persist even to adult life. But usually it is only represented by a funnel-shaped depression at the internal ring.

When present it *predisposes to inguinal hernia*, or it may form the sac of a hydrocele. After leaving the external ring, which in the female is smaller than in the male and lies just external to and a little above the pubic spine, the round ligament expands fan-like to be attached to the connective tissue of the labium majus and the periosteum over the pubic spine.

When the uterus is in its typical position the round ligaments are not taut, but only when there is *backward displacement* or a *prolapse*, hence they play but a secondary rôle in supporting the uterus.

For the displacements just named *Alexander's operation* of shortening the ligaments, and thereby pulling the uterus forward and, if prolapsed, upward, has been often performed. The *incision* is like that for inguinal hernia.

Sometimes there is difficulty in *finding the ligament* and for this purpose the external ring is exposed and the tissues below and internal to it are hooked up and pulled upon, or the canal is slit up for a distance and the contents of the canal similarly dealt with. We may pull down and *shorten the ligament* by as much as four inches in some cases. After pulling down the cord for a certain distance a *pouch of peritoneum* is apt to appear at the external ring. This may represent the canal of Nuck, or more often a new pouch pulled down from the peritoneum at the internal ring. Such a pouch occupying the canal naturally *predisposes to hernia* and the latter has not infrequently followed such operations.

The round ligament is *stronger* than one would suppose and bears a very considerable traction (.5-.6 kgr., according to different observers). In *pregnancy* it becomes four times as stout as in the non-pregnant state. Contraction or preternatural shortness of the ligaments is said to be a cause of anterior displacement of the uterus.

Its *artery*, the *funicular*, is derived like that of the vas deferens from the superior vesical (*i. e.*, hypogastric), as the ligament crosses the latter. It anastomoses with the uterine and ovarian at the uterine end and with the external pudic in the labium.

### The Vagina.

This musculo-membranous *passage way* between the vestibule and the uterus is *directed* upward and backward in the *line* of the pelvic outlet below and the pelvic axis above. It forms an angle of 25 to 35 degrees with the long axis of the body and of 65 to 75 degrees with the horizon, but these measurements vary with the pelvic inclination of the individual and with the condition of the bladder and rectum. Nearly half of it lies below the plane of the pelvic outlet.

Its *walls*, ordinarily in *contact*, present on transverse section an H-shaped fissure. Its *anterior wall* measures  $2\frac{1}{2}$  to 3 inches in length, the *posterior* nearly  $3\frac{1}{2}$  inches. In the *lateral dimensions* it is extraordinarily *dilatable*, admitting the passage of the foetus at birth. The *anterior wall* is in close relation with the *urethra* below and the *bladder* above. The *trigonum vesicæ* and the base of the bladder just above it

are connected with the vaginal wall by connective tissue continuous with the subperitoneal tissue between the cervix and the bladder. So close is this connection, especially with the trigonum, that when the *vagina* is everted like a glove-finger in *prolapse* of the uterus the bladder wall is drawn down with it as a pouch projecting into the vagina (*cystocele*). In complete prolapse the *urethra*, the lower two thirds of which are most *intimately connected with the vaginal wall*, is also inverted, so that from the meatus its direction is downward and backward. When the support afforded by the perineum is weakened by its rupture a cystocele may project into the vagina without uterine prolapse, but, according to Sims, a cystocele always precedes complete prolapse of the uterus.

Owing to prolonged pressure between the foetal head and the pubic bones during a tedious labor, the vesicovaginal septum may slough and give rise to a *vesicovaginal fistula*. Similar fistulae may also occur from a like cause between the urethra and vagina or between the bladder and cervical canal or these three forms of fistulae may be combined in one.

The *trigonum vesicæ* is faintly indicated on the *anterior vaginal wall* as follows: the *base* by a transverse fold of mucous membrane, slightly convex inferiorly, about  $2\frac{1}{2}$  to 3 cm. below the external os uteri, and the *sides* by two folds which diverge from the upper end of the anterior columnæ rugarum. Pawlik used these markings in *catheterizing the ureters*, whose openings are at the upper angles of the trigonum, but we have a surer way in Kelly's method through a urethral speculum. Above the base of the trigonum the *ureters pass upward and outward diverging somewhat so as to reach the upper end of the lateral vaginal walls, where they occupy the triangular space between the levator ani muscle and the vagina. Calculi lodged in the lower inch or two of the ureters may therefore be felt and removed through the upper part of the vagina.*

The *lateral walls* of the vagina are in *contact* above with the *base of the broad ligaments* and their contents, including the uterine vessels. Hence we can here palpate or expose these parts by incision (see Broad Ligaments, p. 390). In its lower two thirds the *lateral vaginal wall* is in contact with the rectovesical fascia and the antero-internal border of the levator ani muscles as well as with the vaginal vessels.

The *posterior vaginal wall* is in *contact* with the *rectum* from which its upper fourth ( $\frac{3}{4}$  inch or so) is *separated by the peritoneal pouch of Douglas*, its middle portion by *areolar tissue*, continuous with the subperitoneal connective tissue, and its lower end by the *perineal body*. Hence we can *palpate* through the vagina the *contents* of the lower end of *Douglas' pouch*, whether this be the coils of intestine, normally present, or a retrouterine haematocele, a retroflexed uterus, a uterine fibroid, or a displaced and perhaps cystic ovary or tube. Through the upper end of the posterior vaginal wall we may *reach by incision the peritoneal cavity* in *Douglas' pouch* and through this incision break up adhesions behind the uterus or reach its adnexa. The peritoneal cavity may also be opened by *traumatism inflicted through the vagina*,

and through such an opening intestinal coils may protrude. Rarely the intestinal coils occupying Douglas' pouch may protrude from above and behind into the vagina as an *enterocele*, or lower down the rectum may form a similar pouch or *rectocele*. Such a pouch does not necessarily accompany a prolapse of the uterus with eversion of the vagina, for the latter is more loosely connected with the rectum than with the bladder and may not pull it down. Similarly in prolapse of the rectum the vagina is not necessarily pulled down.

Although the *rectovaginal septum* does not suffer from pressure as does the vesicovaginal, yet it may be torn through even to a high level at childbirth. If such a complete rupture is not healed throughout it may leave a *rectovaginal fistula*.

The *upper end* is the *largest part* of the vagina. Its angle of reflection onto the cervix is known as the *fornix* and should be supple when normal. Into this upper end the intravaginal portion of the cervix projects at an angle. (See Uterus, p. 381.) The *line of vaginal attachment* is *oblique* from behind forward and downward, making the *posterior vaginal fornix* much *deeper* than the anterior and the *posterior vaginal wall* longer than the anterior, so that it may sometimes be difficult to reach the limit of the posterior fornix with an examining finger of moderate length.

The *lower end* is the *narrowest part* and may be still further *narrowed by* the engorgement of the *bulbs of the vestibule*, which flank it on either side, and by the contraction of the constrictor or *sphincter vaginae* and perhaps also of the levatores ani. The spasmotic contraction of the constrictor vaginae known as *vaginismus* may interfere with coitus. It may require surgical treatment, but the surrounding parts should first be carefully inspected to discover if possible some cause of reflex irritation. As the vagina near its lower end *pierces* the *triangular ligament*, this part of the canal is also the most resistant to dilatation. The lower end, *orificium* or *introitus vaginae*, is partly shut off from the vestibule in the virgin by an *imperfect septum*, the *hymen*. This membranous fold varies much in *shape*, but it is usually crescentic and attached behind and laterally, having an opening in front, though it may form a complete septum with one, two or several small openings or, occasionally, with no opening (*imperforate hymen*). The latter condition causes a damming back of the menstrual flow which fails to appear and, unless relieved, distends the vagina, the uterine canal and even the tubes, and hence calls for surgical relief. Although the hymen is usually *ruptured* by the first coitus it may not be until parturition, hence it is not a proof of virginity nor is its absence incompatible with virginity. After parturition remains of the hymen appear as rounded elevations (*carunculae myrtiformes*) around the *orificium vaginae*.

As to *structure* the very *elastic* vaginal mucosa, lined by stratified epithelium, is destitute of glands, hence vaginal discharge is of the nature of a transudation. Beneath the mucosa is a rich *venous plexus* which may be regarded as *erectile tissue* and may become varicose and

form a pile-like tumor near the external orifice. In infancy and childhood the vagina is often relatively long, corresponding to the high position of the pelvic viscera; in old age it undergoes atrophy and sometimes partial closure. Congenitally it may be more or less completely divided by a vertical septum into lateral halves, usually connected with the halves of a bifid uterus. It may also be very small and rudimentary or even wanting. In the latter conditions other parts of the genital system, uterus and ovaries, are likely to be rudimentary or wanting.

FIG. 92.

Sagittal section of the vagina and neighboring parts. (GERRISH, after TESTUT.)

### The Female Urethra.

This represents the prostatic and membranous portions of the male urethra and, like the latter portion, passes through the two layers of the rather indistinct triangular ligament and the striped muscular fibers representing the compressor urethrae muscle (deep transversus perinei) and possibly the prostatic fibers also. The striped fibers surround the urethra as a *sphincter* in its upper 1 cm. only, where it is connected to the vagina by loose connective tissue; in the lower part of the urethra, where the urethral and vaginal walls blend to form the urethrovaginal septum (1 cm. thick above), these fibers occur in front only. Circular unstriped fibers around the vesical end form a powerful *sphincter*. As may be proved by distension of the bladder in the cadaver, no muscular action of the sphincters is necessary to retain urine, provided there is no vis a tergo through abdominal pressure or the contraction of the bladder.

The *urethra* may be *felt* between the anterior vaginal wall and the pubes like a *round cord*. The female urethra measures  $1\frac{1}{2}$  to  $1\frac{1}{2}$  inches

in length. In the erect position it is *directed downward and slightly forward*, nearly parallel with the vagina though inclining slightly more forward below. Hence its lower end is further from the vagina than the upper end. It is *slightly convex* backward yet not enough to interfere in any way with the passage of a straight catheter. Its *exit from the bladder* is a little below and an inch behind the middle of the symphysis. It passes  $\frac{3}{5}$  to  $\frac{4}{5}$  of an inch *below the subpubic arch* and its *external meatus*, usually a *sagittal fissure*, is found near the base of the vestibule on a papilla one inch behind the clitoris. It is possible after practice to *pass a catheter* without exposure of the parts by means of the latter measurement, or better by means of a *tubercle* just behind the meatus at the lower end of the anterior columna rugarum of the vagina. In children and when the parts are swollen, as after a difficult labor, the meatus is relatively far back and difficult to find.

The *meatus* is the *narrowest part* of the canal, which averages 7 to 8 mm. in diameter, but it is extremely *dilatable* as it is not surrounded by dense resisting structures as in the male. Thus it may be *gradually dilated* under an *anæsthetic* so as to allow the removal of small calculi or foreign bodies, and the introduction of the finger for exploration or of the cystoscope for examination or ureteral catheterization. The resulting *paralysis*, if it occurs, quickly disappears unless the dilatation has been too great and too abrupt, when it may persist, as reports of cases show. In cases of imperforate hymen and narrowness or absence of the vagina the urethra has even become the channel of sexual intercourse.

In the *submucosa* is a *cavernous venous plexus* which gives the mucosa a darkish hue during life and may become *varicose* and form a pile-like tumor near the meatus. Small vascular tumors (*papillary angioma*) may spring from the mucous membrane at or near the meatus, especially in its posterior segment. These "*urethral caruncles*" bleed readily and are highly sensitive and sometimes very painful, so as to give rise to marked local and general symptoms and to demand removal.

Since the female urethra is a short wide tube which serves the purpose of a urethra only, *inflammation* is less common, less severe and easier to treat than in the male, and the resulting stricture is correspondingly less common and less complete and often requires no treatment.

## EXTERNAL GENITALS.

## A. FEMALE EXTERNAL GENITALS.

The vulva is really a *cleft-like space* between the rima pudendi (the fissure between the two labia majora) inferiorly, and the hymen or its remains superiorly. It includes all the other external genitals in the female. The two **labia majora** represent the two lateral halves of the scrotum in the male and, like it, are composed of skin enclosing an imperfectly developed *dartos*, and are subject to the same *pathological conditions*. They are the usual situation of elephantiasis in the female, are greatly swollen in cases of oedema and may contain large extravasations of blood (pudendal haematocele) after injury. They contain a considerable amount of fat, with whose fibrous capsule and partitions the round ligament is connected. *Inguinal herniae* (sometimes containing the ovary) may descend into them anteriorly, *pudendal herniae*, which escape between the vagina and the pubic ramus more posteriorly. Cystic collections, probably in the unclosed canal of Nuck and known as "*hydrocele in the female*," may also occur in the labia majora.

Their point of meeting posteriorly, the *posterior commissure* or *fourchette*, is an inch or more in front of the anus and limits the base of the perineal body anteriorly. The fourchette is often torn in parturition and is the common seat of chancres in the female.

The **labia minora** or **nymphæ** contain much vascular tissue and are not infrequently redundant, projecting below the vulva, especially in certain races (*i. e.*, Hottentots, etc.). On approaching the median line anteriorly they *bifurcate* and their branches unite from side to side to form the *preputium* and the *frenulum* of the clitoris. Extravagant importance has been attached by some to the adhesion of this prepuce to the clitoris as a cause of various symptoms.

The **bulbi vestibuli**, two pyriform masses of erectile tissue corresponding to the lateral halves of the bulbs of the male urethra, lie on either side of the orifice of the vagina and extend thence on either side of the vestibule, beneath its mucous membrane, to a point below the clitoris, where the two connect. Rupture of the bulb may occur from injury, especially during pregnancy when they are enlarged, and results in the formation of a large haematoma (*pudendal haematocele*).

Behind the bulbi vestibuli and on either side of the posterior half of the vaginal orifice lie the two **vulfovaginal glands** (*the glands of Bartholin*), which probably represent Cowper's glands in the male. The *ducts*, three quarters of an inch long, open just outside of the vaginal orifice and opposite its center, where the opening may often be seen as a small red depression on evertting the nymphæ and pressing the hymen inward. The *glands* are one third to one half inch long, lie beneath the superficial perineal fascia and, like the bulbi vestibuli, are *covered externally by the sphincter vaginæ muscle*. The duct and gland are liable to *inflammation* and *suppuration*, often of gonorrhœal origin. The resulting *vulfovaginal abscess* is felt in the base of one of the

labia majora and causes oedema there. Cystic dilatation of the duct is not infrequent. These glands atrophy after the menopause if not before. In general the vessels and nerves of the external genitals correspond to those of the homologous parts in the male; thus the lymphatics enter the inguinal nodes.

## B. THE MALE URETHRA AND EXTERNAL GENITALS.

### The Male Urethra.

The urethra is to be regarded as a *closed valve* whose walls are usually in contact. It is a *canal* only when open for the passage of urine, semen or instruments.

FIG. 93.

The male urethra, laid open on its anterior (upper) surface. (GERRISH, after TESTUT.)

**Divisions.**—In its passage from the bladder at the vesical outlet, or internal meatus, to the external meatus it is divided in various ways according to (1) the parts through which it passes (prostatic, membranous, spongy, etc.), (2) its fixity and mobility, (3) its direction (curved or straight), (4) its pathological and therapeutic peculiarities (anterior and posterior urethra).

The **prostatic urethra**, 1 to  $1\frac{1}{4}$  inches long, is spindle-shaped. Its upper narrowed end, the *vesical outlet* or internal meatus, is formed by the *annulus urethralis* (see p. 369). The latter is as a rule quite *dilatable* but may become thickened or more resistant as the result of spasmodic action during micturition in gouty subjects or in those with chronic urethral trouble. In such cases the condition may be relieved by stretching, with or without a slight incision. If in such cases the prostatic sinus is deep the beak of the catheter or sound may impinge on its posterior wall, under the back of the annulus, and thus enter the bladder with difficulty if at all.

The central dilated part of the prostatic urethra presents an *inverted U* on cross section, owing to the median projection from behind of the **verumontanum**. This contains *erectile tissue* and

may serve to close the upper end of the urethra and prevent the passage

of semen back into the bladder. On its summit in the median line is the fair sized opening of the sinus pocularis, or *uterus masculinus*, the homologue of the uterus. This blind sinus runs upward and backward for one fourth to one half of an inch beneath the "middle lobe." On either side of it run the *ejaculatory ducts*, whose slit-like openings are on either side of (sometimes within) that of the sinus. In the two depressions or *prostatic sinuses*, one on either side of the verumontanum, open the *ducts of the glands of the prostate*, of which two are larger and more noticeable. The tip of a sound may lodge in the prostatic sinuses, especially in cases of prostatic enlargement. To avoid this the beak of a "prostatic catheter" is longer and curved further forward and the flexible catheters are made with the tip bent up (Mercier catheter). The tip of a small sound or bougie may also lodge in the sinus pocularis unless it is made to hug the upper wall. On account of the various openings into the prostatic urethra we can understand how an *inflammation* of this part *may extend* (1) into the bladder and thence to the ureters and kidneys, (2) into the ejaculatory ducts and thence to the seminal vesicles or along the vas deferens to the epididymis, etc., or (3) into the substance of the prostate.

In the erect position the *course of the prostatic urethra* is *nearly vertical* with a slight concavity forward. It runs in front of the middle of the upper two thirds and about the middle of the lower one third of the gland, though cases have been observed when it has merely occupied a groove on its anterior surface. The prostatic portion is not only of *large caliber* but also *very dilatable*, readily admitting the passage of the finger in operations on the urethra or bladder. Stricture is unknown in this part though congenital folds and pockets may occur here and interfere with micturition. The lower half of the prostatic urethra may be *incised* in the median line without injuring other structures. Median incisions in the upper half must be in the exact median line to avoid the ejaculatory ducts.

The **membranous portion**, or that lying between the two layers of the triangular ligament is *directed* obliquely downwards and forwards and forms the beginning of the subpubic curve. It is, next to the external meatus, the narrowest segment and measures about half an inch in *length*, though the floor is said by some to measure less than the roof owing to the projection backwards of the bulb along the floor. It is *surrounded by* the *compressor urethrae muscle* which forms (1) the voluntary sphincter, (2) the dividing line between the anterior and posterior portions of the urethra, and (3) the cause of the so-called spasmoid strictures. Close *behind* it lies the bend in the anterior wall of the *rectum* between the anal and pelvic portions. At this point an instrument can be felt within or guided into the membranous urethra, or the false passage of an instrument may be felt by the finger in the rectum. Beneath and on either side lie the bulbourethral glands (*Cowper's glands*) the homologue of the glands of Bartholin in the female. Enclosed by the compressor urethrae muscle and resting on the upper surface of the superficial layer of the triangular ligament,

one fifth of an inch apart, these glands thus lie above and behind the bulb. The formation of *cysts or abscess* may occur in them, the latter by extension of gonorrhoeal inflammation from the bulbous urethra, into the floor of which their *ducts* ( $\frac{2}{3}$  to 1 inch long) open. They atrophy as age advances.

The spongy portion,  $5\frac{1}{2}$  inches in *length*, includes several *subdivisions*. The bulbous portion, about an inch in *length*, is the most posterior. Immediately in front of the triangular ligament the bulb at first covers only the floor and then gradually the sides, while the front of the urethra is only covered by spongy tissue  $\frac{1}{5}$  to  $\frac{2}{5}$  of an inch lower down, so that some authors call the portion not covered by the bulb the *præ-diaphragmatic* or *prætrigonal portion*. The front wall of the latter portion is thinner than elsewhere. Along the *floor* of the bulbous portion the urethra is much *dilated* and this dilatation (*fossa bulbi*) passes suddenly, not by a gradual narrowing, into the narrow and firmly fixed membranous portion at the point where the latter pierces the firm anterior layer of the triangular ligament. This is the *critical point in the passage of instruments*, for if the instrument is allowed to follow the floor it sinks into the dilatation of the bulb below the level of the membranous portion and then impinges on the triangular ligament, or if pressed *too closely* against the thin dilatable anterior wall a like result may happen. To enter the narrow opening of the *membranous urethra* ("neck of the bulb" as the French call it) the *sound* should be kept along the *roof* of the urethra and as large an instrument as will pass should be used, for it is less likely to catch. We have seen that hugging the roof is also the rule in passing the prostatic portion to avoid catching in the sinuses and the annulus.

The bulbous portion continues the *subpubic curve*, commenced in the membranous portion, and in the erect position it forms the *most dependent part of the fixed portion* of the urethra. Hence the products of inflammation naturally gravitate here and, as the parts are bathed in pus, chronic inflammation is apt to linger here and its results are seen in the *common occurrence of stricture*. The chronic inflammation, or *gleet*, alters the lining mucosa so that plastic material is deposited beneath it to prevent the soaking of urine into the surrounding tissues. The natural contraction of this plastic exudate narrows the lumen and so results in stricture and this keeps up the irritation and the discharge, which is only cured by the cure of the stricture. The bulb is *covered externally* by the accelerator urinæ muscle.

In front of the bulb the urethra continues in a fixed position, nearly horizontally, but with a slight upward inclination, to a point beneath the suspensory ligament. In front of this ligament the urethra is movable with the penis. The *caliber* of the spongy urethra is fairly uniform between the bulb and the *fossa navicularis*, the dilatation in the glans penis, especially along the urethral roof. At its distal end this fossa ends in the *external meatus*, a vertical slit on the antero-inferior aspect of the glans. The meatus is the *narrowest and least dilatable portion* of the urethra so that any instrument which can pass the

## PLATE XLVII.

FIG. 94.

Proximal portions of urethra, with surrounding parts.  
(Gerrish, after Testut.)

FIG. 95.

Outline diagram of the curved portion of the urethra,  
showing the distances from and the relations of the  
different parts to the symphysis. (Testut.)

meatus should pass the rest of a normal urethra. To allow the use of large sounds or instruments in the treatment of pathological conditions of the rest of the urethra or the bladder (*i. e.*, litholapaxy, cystoscopy of the bladder, etc.) the meatus must be *enlarged by slitting it inferiorly* in the middle of the frænum. The meatus may be *congenitally small*, even admitting only a fine probe. This condition is often associated with congenital phimosis, and from it urethral spasm may result, though perhaps less often than formerly supposed by many. Besides the many mucous glands found in all parts of the urethra, especially in and near the navicular fossa, the small pits or *lacunæ of Morgagni* occur in the spongy portion in longitudinal rows, a median row of larger lacunæ on the anterior or upper wall and a row of smaller lacunæ on either side of it. As the *openings* of these lacunæ are *directed toward the meatus* the larger ones may catch the tip of a small sound or bougie, thereby interfering with treatment or misleading the diagnosis. Hence instruments should be passed along the lower wall or floor of the spongy portion. An additional reason for this is found in the presence of a lacuna of large size, the *lacuna magna*,  $\frac{1}{2}$  to 1 inch from the meatus in the roof of the navicular fossa, which may easily arrest the point of an instrument. It is nearly covered below by a semilunar valve-like fold (the valvule of Guerin).

According to its fixity the urethra is divided into a **fixed** and a **movable part** (*pars fixa* and *pars mobilis*). These divisions do not correspond to the preceding but more to the next following division for the **fixed portion** includes the prostatic, the membranous and the proximal two inches of the spongy portion, or as far as the anterior border of the suspensory ligament. The *membranous portion* is the *only absolutely fixed part* and therefore of the greatest importance in catheterization, for we must direct the catheter to and through it; its position does not change to suit the catheter. The *bulbous portion* is the *most movable part of the fixed portion* and this part lies immediately in front of the most fixed portion. This is one reason for the difficulty of directing the point of the catheter or sound into the membranous portion, for the bulb may be easily pushed backward or sideways. The *rest of the spongy portion* of the urethra is the **pars mobilis**, and it depends for its position and direction upon that of the penis. For the introduction of instruments this portion may be put in the most suitable position for the purpose.

In direction the urethra is median but may deviate somewhat laterally in micturition. It presents a *curve*, concave forward and upward, beneath the symphysis, the **subpubic curve**, and a **prepubic curve** where the fixed and movable portions join. The latter curve, with its concavity downward, is at the junction of the fixed and movable portions and is present in the flaccid state of the penis but is obliterated when the penis is erected or raised up. Hence in the passage of instruments we raise the penis and have to deal only with the **subpubic curve**. The latter curve is *most marked in the membranous and bulbous portions*, though it is continued slightly in the upward

direction in the prostatic urethra, which is nearly vertical, and in the forward direction about to the prepubic curve or the end of the fixed portion, though the anterior portion of this rises but little ( $\frac{1}{5}$  to  $\frac{1}{4}$  inch) above the level of the lowest point of the curve. The curve (Fig. 90) is described as being an *arc of a circle* having a *diameter* ranging, according to different authors, from  $3\frac{1}{4}$  to  $4\frac{4}{5}$  inches, the chord of the arc measuring about  $2\frac{1}{5}$  to  $2\frac{3}{4}$  inches. The curve is sharper in small, thin men and flatter in large stout men. The subpubic curve belongs to the fixed portion of the urethra and hence metal urethral instruments are made with a definite curve to allow them to take the curve of the urethra without letting the tip impinge or catch on the floor. It is possible to pass a stiff straight, or nearly straight, instrument into the bladder but not without painful tension of the connections of the urethra, especially the suspensory ligament, and hence it is often done under anaesthesia and only for certain objects, as litholapaxy, etc.

The *division* into *anterior* and *posterior* urethrae occurs between the membranous and the bulbous portions at the level of the superficial layer of the triangular ligament. This division is of *practical importance* from a pathological, prognostic and therapeutic standpoint. The discharge from a *urethritis of the anterior urethra* drips from the meatus and injections into this part escape at the same point. A urethritis also is often limited to this part for the compressor urethrae muscle offers an obstacle to its further extension. The complications of such an anterior urethritis are principally chordee, gleet and stricture. When an *inflammation* extends into the *posterior urethra* or an injecting catheter is introduced beyond the compressor urethrae muscle the discharge or injection flows into the bladder and does not appear at the meatus. The inflammation here is also liable to spread to the bladder, vas deferens, epididymis, seminal vesicles, prostate and kidneys by continuous extension or otherwise, hence the prognosis of posterior urethritis is more grave. By using considerable pressure and preventing the escape at the meatus fluid may be injected into the bladder from any point in the anterior urethra.

*Embryologically* also the posterior urethra is of a different formation (*i. e.*, from the urogenital sinus) and corresponds to the urethra and vestibule in the female, while the anterior urethra is formed by the genital folds of the external genitals.

The *length* of the urethra from the internal to the external meatus varies, but averages about seven inches. It varies with the length of the penis; when the latter is contracted to the utmost it may be considerably (over an inch) shorter, when the penis is more or less erected or is pulled upon during catheterization the urethra may measure eight inches or more. Hypertrophy of the prostate also lengthens the urethra, a fact which is useful in the diagnosis of this condition. The length of the urethra at birth is 5–6 cm., in children of five years 8–10 cm., at the beginning of puberty 10–12 cm.

The normal *caliber* or *diameter* of the urethra, being that of a cylinder which separates the walls without stretching them, can only be

given approximately except for the external meatus. Sappey states that, exclusive of the meatus, the *urethral circumference* ranges between 15 and 18 mm., so that a No. 15 (French) sound could be passed without stretching the canal. The *meatus* is about  $\frac{1}{4}$  of an inch in its long diameter. Of more practical importance is the **absolute or relative distensibility**, which *averages* 10.5 mm. in its diameter (Joessel, Waldeyer). The distensibility *varies* in different parts and as we pass from end to end of the urethra we find that a *narrow portion alternates with a wider portion*. Thus the narrow portions are, in order, the external meatus, spongy portion, membranous portion and internal meatus; the wider portions are the fossa navicularis, the bulbous portion and the prostatic portion. In order of distensibility we find the meatus the least distensible, next the membranous portion, the spongy portion, the prostatic portion and lastly the bulbous portion, which is the most distensible. The different parts should distend so as to admit the following sounds of the French scale: the meatus No. 24, the spongy portion Nos. 28–30, the bulbous portion No. 32, the membranous portion Nos. 26–27, and the prostatic portion Nos. 30–32.

Otis proved that the distensibility of the urethra was greater than formerly supposed, though Guyon showed that by the passage of large sounds, 31–34 (French), on the cadaver lacerations were produced, especially on the floor of the penile portion. According to Otis there exists a constant *ratio of nine to four* between the circumference of the *penis* and that of the distended *urethra*. Apart from the fact that it is improbable that such an exact mathematical ratio is constant, it is difficult in measuring an organ, so variable in size as the penis, to measure the latter in the same condition of relative size in different cases. Still Otis' law is of value as a practical guide to the surgeon.

The **relative position** of some parts of the urethra may be more fully given. The **internal meatus** is on a level with the middle of the symphysis, or somewhat below or above it. It lies above this point in young subjects, and not infrequently in adults. The **prostatic portion**, in whole or in great part, lies above the horizontal plane passing through the bottom of the symphysis, so that this portion is often entirely behind the symphysis. The **deepest point** of the **subpubic curve** is in the bulb and lies 18 to 20 mm. from the subpubic angle, usually more or less behind the vertical plane of this angle, but sometimes beneath or even in front of it. We have already referred to the effect on the frequency of stricture here of its being the most dependent point of the curve in the erect posture. The **prepubic curve** lies below the horizontal plane of the subpubic angle, and usually  $\frac{1}{5}$  to  $\frac{1}{4}$  of an inch above the lowest level of the urethra in the bulb, so that from the latter the urethra extends slightly upward as well as forward, though it may be horizontal. *Between the subpubic curve of the urethra and the symphysis lie the dorsal vein of the penis, the pudendal plexus and the continuation of the perivesical fat.*

On **cross section** the empty urethra is represented by a fissure which is vertical at the external meatus, transverse in the spongy portion,

stellate in the membranous portion and like an inverted U in the prostatic portion. A form of rifling is involved by this progressive change in shape which may account for the spiral form of the normal stream of urine. In addition the mucous membrane of the collapsed urethra is in longitudinal folds.

**Sphincters of the Urethra.**—The fixed portion of the urethra passes through a continuous layer of encircling muscle fibers, both plain and striated. This is formed of several parts, of which the most distal is the bulbocavernosus muscle. The **internal sphincter** is composed of plain muscle fibers, derived from the deep layers of the trigonum, which pass downward and forward obliquely encircling the upper part of the prostatic urethra and meeting in front of it. This does not include but is *below* the circular fibers of the bladder which are aggregated around the internal meatus and form a ring, the "*annulus urethralis*," which is completed posteriorly by the trigonal muscle. The **external or voluntary sphincter** is composed chiefly of the fibers of the compressor urethrae muscle, though striped fibers continuous with them surround the lower half of the prostatic urethra, especially in front. Distally the compressor urethrae adjoins the bulbocavernosus muscle.

The urethral walls also contain *unstriped longitudinal fibers*, continuous with those of the bladder, and some circular fibers, as far as the lower end of the bulbous portion. There is but little muscular tissue in the walls of the movable portion (*pars mobilis*). The muscular tissue of the urethra appears to have a *peristaltic action*, whereby a catheter left in the urethra or the last drops of urine are gradually expelled. Cases of *reverse peristalsis* are also known where a flexible instrument insecurely tied has been pressed into the bladder. As already noted the **external sphincter** is the dividing line between the anterior and the posterior urethra and is also the cause of *spasmodic stricture*. The latter is usually due to a reflex from some point of irritation in the urethra (stricture, granular patch, etc.), and is often caused by the rough use of instruments; occasionally it may be due to an abnormally small meatus. It commonly yields to steady easy pressure. The retention of urine following operations on the rectum, anus, etc., is thought by many to be the result of vesical inhibition rather than urethral spasm.

**Changes According to Age.**—In *children* the urethra is *shorter* (see page 402) and *narrower*, but Keegan has shown that the urethra of a male infant one year old will admit instruments for litholapaxy, and that at two to three years of age a No. 9 and at eight to ten years a No. 11 lithotrite may be passed. Hence lithotrity and litholapaxy may be performed upon quite young infants. The *subpubic curve* in infants is also sharper, owing to the high position of the bladder. In *old age* there occurs a dilatation of the fossa of the bulb and, in cases of enlarged prostate, a lengthening and narrowing of the prostatic portion, often with an increased forward curve of the vesical end which tends to make the tip of instruments catch on the floor, in the prostatic sinus

**Catheterization**, or the introduction of instruments, is of such importance that we may repeat what has been said in different places above. Use the largest instrument that will readily pass as it is safer and easier and sometimes passes where smaller sizes will not. In the *spongy urethra* pass the instrument, especially if it be small, along the floor to avoid catching the tip in the lacuna magna, or in the dorsal row of large lacunæ behind it. The *movable urethra* (*pars mobilis*) accommodates itself to the shape and direction of the instrument, which is commonly held over and parallel to Poupart's ligament, the penis being held upwards and to either side to obliterate the prepubic curve. When the *bulb* is reached the handle of the instrument, now held in the median line, is depressed to elevate the tip to the roof so as to find the opening into the *membranous portion*. The finger in the rectum or perineum may also help to raise the tip of the instrument. If *spasm* exists use only slight steady pressure, principally the weight of the instrument; never press hard. Most *false passages* start from the depressed floor of the fossa bulbi, posteriorly. The tip of the instrument should continue to follow the roof of the membranous and *prostatic urethrae* so as to follow the curve of the urethra and to avoid the utricle and prostatic sinuses; this is done by a gentle depression of the handle.

The urethra may be **ruptured** by being crushed between the pubic arch and a hard substance, astride of which the patient falls. The parts of the urethra most often injured are the membranous and bulbous portions, the latter especially when the body is bent forward, when a considerable length of the spongy urethra may be crushed.

The commonest pathological conditions that affect the urethra are urethritis, usually gonorrhœal, and its sequelæ, gleet and organic stricture. The latter, as stated above, is most common in the bulbous and membranous portions, as is also stricture following rupture of the urethra. The obstinacy of a urethritis in yielding to treatment is in part due to the length and narrowness of the canal, to the dilated portions which serve as reservoirs for secretion and to the numerous folds, lacunæ and glands.

### The Penis.

The **skin** covering the body of the organ is continuous with that of the scrotum and is destitute of fat, highly elastic, thin and very movable. Owing to the latter fact, due to the looseness of the subcutaneous tissue, the skin should not be drawn too strongly downwards over the glans in circumcision or amputation of the penis, otherwise the operator may be startled by seeing the skin above the section retract to the base of the organ. In very large scrotal herniæ or hydroceles the skin and loose outer coverings of the penis may be drawn upon to such an extent to cover the scrotal mass that the penis represents a mere depression in this mass from which the urine escapes.

From the cervix the skin extends down over the glans a variable distance and is then doubled upon itself to form the **prepuce** or **foreskin**. The **inner layer** of the prepuce is attached more or less firmly around

the cervix to be thence continued over the glans, at the end of which, dipping into the meatus for a quarter of an inch, it is continuous with the urethral mucosa. The prepuce *at birth* is relatively very long, more than covering the glans.

When the prepuce is so tight as to prevent its easy retraction the condition is called **phimosis**. The preputial orifice may only admit a small probe or, rarely, may be completely closed. Phimosis may cause *difficult micturition*, if the opening at the end of the prepuce is very small, and in any case *balanitis*, which is due to retained secretions and is followed by adhesions of the prepuce to the glans. Incomplete development of the glans, incontinence of urine, especially nocturnal, and greater liability to contract venereal diseases may also result from phimosis. A long series of reflex nervous conditions has been attributed to the same cause, often without sufficient reason. Besides the congenital form, phimosis may also be acquired as the result of inflammatory swelling, due to the presence of ulcers or balanitis beneath the prepuce.

Owing to the serious conditions resulting from phimosis it requires appropriate **treatment**. In many cases of congenital phimosis *stretching* the prepuce may be all that is necessary, in others a little *dorsal slit* is sufficient, while still others with a long narrow foreskin require **circumcision**. The main object of this is to uncover the glans. It is unnecessary, if it is possible, to divide the two preputial layers at the same level, at the base of the glans. No special instruments are required. We divide the outer layer at the proper level, then slit up the inner layer, which covers the glans on its dorsum. Then we can loosen the adhesions with the glans which, when present, prevent the two layers being cut at the same level. We leave a cuff of the inner layer of varying size and suture the two layers. It is interesting to note that shortly before birth the inner layer of the foreskin and the glans are adherent throughout.

When a foreskin, narrow from birth or as the result of inflammation, is forcibly retracted over the glans it may remain caught in the cervix owing to the difficulty of pulling it down over the corona. The pressure, especially that of the narrowest part, the preputial margin, causes the glans to swell, which decreases the chance of reduction and increases the pressure so that sloughing occurs at the line of pressure. This condition, called **paraphimosis**, demands relief to save the glans, etc., from sloughing. We may sometimes replace the foreskin after reducing the size of the glans by pressure, but other cases require a longitudinal incision on the dorsum, over the constricting band and down to the sheath of the corpus cavernosum. In the median line inferiorly there is the indication of a *median raphé*, continuous with that of the scrotum, along which the coverings of the penis are more or less adherent together.

The skin is lined by a thin **dartos**, a muscular layer with longitudinal fibers continuous with the dartos of the scrotum. At the end of the prepuce the muscular fibers are arranged circularly, forming a kind of **sphincter**. The dartos lines both layers of the prepuce between which

is an extension of the **loose subcutaneous tissue**, which connects the skin loosely with the fascia penis and renders the former so *movable*. This loose tissue accounts for the *sudden and great swelling* that may occur in the prepuce or on the penis as the result of inflammation, oedema, or the extravasation of blood, urine, etc. The *superficial vessels and nerves* are contained in this tissue. The skin covering the cervix and the proximal side of the corona is lined by this loose tissue, but there is no subcutaneous tissue over the glans. This accounts for the fact that a *chancere* on the glans shows but little if any induration (parchment induration) while a chancere on the cervix or the proximal side of the corona, a favorite position, has a typical induration of the base, due to the infiltration of the subcutaneous connective tissue.

The **fascia penis** is the highly elastic fibrous sheath investing the three erectile bodies which form the bulk of the penis. It extends as far as the cervix, around which it is firmly attached to the erectile bodies and fuses with the skin. At the base of the pendulous portion of the penis this fascia is continuous with the superficial perineal fascia behind and the suspensory ligament in front. It covers the deep dorsal vessels and the lateral tributaries of the dorsal vein, by compressing which it contributes to the *erection* of the penis, after this condition has once become established. In this it is aided by those fibers of the bulbocavernosi and the ischiocavernosi which encircle the dorsum of the corpora cavernosa and thus compress the dorsal vein. The contraction of the compressor urethrae muscle and the pressure of the penis against the pubic arch by means of the ischiocavernosi muscles also compress this vein and thus assist in erection of the penis. Apart from these causes of erection, which act by hindering the venous return, the vaso-dilator nerves act by increasing the arterial supply of the erectile bodies through the dorsal arteries, the arteries of the bulb and of the corpora cavernosa. The *spinal center of erection* is in the lumbar enlargement and may be stimulated by any local irritation; it also receives exciting and inhibitory stimuli from the brain. When the cerebral inhibitory action is shut off, by an injury or disease of the spinal cord above this center, there is liable to be a condition of chronic partial erection, known as *priapism*.

Besides the active erection, in which arterial supply and venous return are both concerned, there may be a *passive erection*, such as that due to the pressure of a full bladder on the venous plexus (prostatico-vesical) through which the dorsal vein of the penis empties into the branches of the internal iliac vein. The proposal to tie the dorsal vein to assist an incomplete erection of the penis has been tried with some success. A constricting band around the penis causes rapid and extensive swelling of the organ, hence in tying in a catheter it is best not to employ tapes around the penis and no bandage around the penis should be tight. The large deep *dorsal vein* (Fig. 96) of the penis is usually single and occupies the groove between the two corpora cavernosa superiorly. It pierces the triangular ligament one half inch below the pubic arch. The thick elastic sheath of the corpora cavernosa,

called *tunica albuginea* from its whitish appearance, consists of an outer layer of longitudinal fibers covering both corpora and an inner layer of circular fibers forming a separate sheath for each. The latter forms a septum between the two which is incomplete anteriorly so that any inequality in the blood supply of the two corpora may be equalized.

The **suspensory ligament** of the penis connects the corpora cavernosa with the front of the symphysis pubis. In front of this ligament we have the movable portion or "*body*" of the penis, which serves as the pars copulatrix and corresponds to the pars mobilis of the urethra. The angle of the penis, immediately in front of the suspensory ligament, is only present in the flaccid condition of the organ. In erection the "*body*" of the penis comes into line with the "*root*," which corresponds to the two crura of the corpora cavernosa which, diverging behind the suspensory ligament, are attached to the ischiopubic rami.

Each *corpus cavernosum* measures about  $6 \times \frac{1}{2}$  inch, which increases by a third or more in erection. The *corpus spongiosum* begins behind in an enlargement, the bulb, surrounding the floor and sides and, further forwards, the entire urethra. It ends in front in a heart-shaped enlargement, the glans penis, which overlaps the rounded anterior extremities of the corpora cavernosa. The bulb, measuring  $1\frac{1}{2}$  inches long and  $\frac{3}{4}$  inch broad, abuts against the central point of the perineum,  $1\frac{1}{2}$  cm. in front of the anus. It presents inferiorly an incomplete median septum, indicated on the surface by a slight furrow, hence if the bulb is incised in the exact median line the bleeding is less than it otherwise would be. The bulb is invested by a fibromuscular sheath, continuous with the superficial layer of the triangular ligament, and by the *bulbocavernosus muscle*, whose *action* assists in ejaculation, in expelling the last drops of urine and in the erection of the penis. The glans is twice as long on its upper as on its under surface and its projecting base or corona, which limits the cervix, is interrupted in the median line inferiorly by a small median fold, the *frenum preputii*, continuous with the inner layer of the prepuce. The frenum grooves the under surface of the glans as far as the inferior angle of the meatus, and contains vessels of some size which, if ruptured in coitus, in case the frenum is unusually short, or eroded by chancroidal ulceration, may cause considerable loss of blood. In erection both the glans and the rest of the *corpus spongiosum* are soft as compared with the corpora cavernosa and thus they offer no resistance to the passage of semen or urine.

When a urethritis extends beyond the mucosa and causes an induration of the submucous structures the *corpus spongiosum* loses its elasticity, so that in erection it cannot elongate but acts like the string of a bow and bends down the corpora cavernosa, so that the erected penis is curved backward. This condition, known as *chordée*, is very painful, owing to the traction on the inflamed urethra and *corpus spongiosum*. The erected corpora cavernosa may be "*fractured*" by forcible flexion in coitus and otherwise. Such an injury is irreparable;

it causes an extravasation of blood, interrupts the continuity of the erectile tissue and prevents the straight erection of the penis, for the corpus cavernosum so affected can not lengthen as much as the other, or if both are affected a portion of both can not become erected.

The lymphatics of the penis, including those of the urethral mucosa, enter the inner or middle group of the superficial inguinal lymph nodes. Some of the deeper lymphatics of the erectile bodies may perhaps enter the pelvic lymph nodes.

**Congenital Malformations.**—**Hypospadias**, the commonest form, is due to a partial or complete failure to unite on the part of the genital folds, on the under aspect of the penis. These folds by their union convert the groove between them into the spongy portion of the urethra. This failure to unite may affect the entire length of the spongy urethra, so that the urethral opening is in the perineum; or it may occur at the end and involve only the glans, so that the opening is just back of the glans; or it may occur at any intermediate point. In *complete hypospadias* the corpus spongiosum is wanting or defective, being replaced largely by fibrous tissue which does not lengthen in erection of the penis, so that in this condition the penis is bent sharply downward and backward. Complete hypospadias is one of the elements which go to make up *pseudo-hermaphroditism*.

**Epispadias** is due to a failure of more or less of the urethra to close on its upper aspect. The opening is usually found in front of the symphysis and the condition is often associated with a separation of the symphysis and extroversion of the bladder; hence it is due to malformation at an early period of development. It is more difficult to explain embryologically.

Besides being the most frequent situation for chancroid, condylomata and the initial lesion of syphilis the distal portion of the penis may be affected by cancer. This commonly takes the form of epithelioma of the glans or prepuce and most cases are said to occur when phimosis exists or has existed. The inguinal nodes may be involved early and should always be removed.

### The Scrotum.

Although in descriptive anatomy this term is often applied to the skin and dartos only, yet topographically we must consider with it the other envelopes of the testicle and of the lower part of the spermatic cord. The lax scrotum is admirably suited to protect the testicles by allowing them to move about so readily and thus to escape injury. It will be noticed that the layers of the scrotum correspond to those covering the sac of an oblique inguinal hernia. The left half of the scrotum is commonly larger than the right. In the infant the scrotum is larger above than below, vice versa in the adult.

The skin is thin and transparent, showing an ecchymosis beneath it quickly and distinctly. It is very elastic so that it allows of great distension, as in large herniae, hydroceles and tumors. It is also redundant, so that the loss of a portion by excision or sloughing will not

be missed. Excision of redundant scrotum has been employed in the treatment of varicocele. The skin forms a *single pouch*, but a *median raphé*, continuous with that on the under surface of the penis and in the perineum, indicates its embryological formation from two lateral halves. The more or less transverse *rugæ*, into which the skin is thrown by the contraction of the underlying dartos, favor the accumulation of dirt and moisture, the irritation due to which may account for the epitheliomata and eczema, not uncommon here.

The **dartos** is very vascular and closely lines the skin, especially in the lower part of the scrotum. Its dark reddish color depends upon the unstriped muscle fibers that it contains, the contraction of which causes the *rugæ* of the skin. These *rugæ* are a sign of health; they disappear in enfeebled conditions or under the relaxing effects of heat, and the scrotum becomes smooth and pendulous. *In wounds* of the scrotum, especially with loss of substance, the *contraction* of the dartos is of value in closing the gap. Such a contraction may be stimulated by cold applications or mental emotions, but not by electricity. Conversely warm applications relax the dartos and thus may prevent the inversion of the edge of an incised wound of the scrotum, which interferes with its proper suture. Its contraction is slow and peristaltic and shortens the scrotal pouch. The dartos forms a *separate pouch* for each testis and the median meeting of these two sacs forms the *septum scrota*, which extends from the raphé to the root of the penis. The muscle fibers of the dartos run for the most part longitudinally so that the *rugæ* are transverse. It is *continuous* with the superficial fascia of the groin and perineum and with the dartos of the penis, and like the latter contains no fat.

The *skin and dartos* form practically a *single layer* connected by a loose connective tissue layer with a composite layer formed by the other envelopes of the testicle, etc. For practical and surgical purposes the testis, etc., is covered by only two composite layers, loosely united by this loose connective tissue layer. This loose fatless connective tissue layer allows large *extravasations* of blood to occur after injuries. Owing to the dependent position of the scrotum this tissue may early become very oedematous in a case of dropsy. It allows the testis and cord and their envelopes to be enucleated through an incision or protruded through a wound of the scrotum proper. By many this layer is regarded as *continuous* with the intercolumnar fascia at the external ring and hence as being the *external spermatic fascia*, while others describe the latter as more membranous and as forming a fascial covering of the cremaster muscle. It is continuous with a similar layer in the penis, and thus extravasations of any sort may readily extend from the scrotum to the penis and vice versa. It is also continuous with the deep layer of the superficial perineal fascia.

The **cremasteric and infundibuliform layers**, continuous in the inguinal canal with the internal oblique muscle and the infundibuliform fascia respectively, are lined by the parietal layer of the tunica vaginalis and form a composite envelope for the testis. This envelope is connected

# PLATE XLVIII.

FIG. 97.

The penis in transverse section, showing the bloodvessels and the several layers. (Gerrish, after Testut.)

Transverse section of the right spermatic cord with the layers of the scrotum covering it.

by the loose connective tissue layer with the scrotum proper and hence is readily separable from the latter.

The **cremaster** is a voluntary muscle occurring in scattered, arched bundles, bound together by thin connective tissue laminæ, which also form the sheaths of the muscular bundles. These bundles lie in front of (not behind) the sac formed by the next layer. It is supplied by the genital branch of the genitocrural nerve. Its contraction suddenly raises the testis and its inner coverings, within the scrotal pouch. The **cremasteric reflex** is the reflex contraction of this muscle following stimulation, as by scratching, of the skin of the upper and anterior aspect of the thigh, which is supplied by the crural branch of this nerve. The muscle becomes *hypertrophied* when the size or weight of the enclosed mass is increased, as in large herniæ, etc. According to Toldt its contraction favors the venous circulation within the scrotum and helps to press out the contents of the epididymis.

The **infundibuliform fascia** (*internal spermatic fascia*), by its direct connection with the lower part of the posterior border of the testis, anchors the latter in the postero-inferior part of the scrotum, so that it retains this position when the cavity of the tunica vaginalis is filled with the fluid of a hydrocele or a haematocele. Hence we puncture a hydrocele in front and above, to be out of reach of the testis. At the point of attachment of the testis the infundibuliform fascia is also adherent to the overlying layers, including the dartos and skin. The adhesion together of all these layers forms the *ligamentum scrotale*.

Loose areolar tissue, continuous with the *subperitoneal connective tissue*, connects the infundibuliform fascia with the tunica vaginalis and binds together the various elements of the spermatic cord. In the latter situation it contains some fat and is the seat of *fatty tumors of the cord*, which occasionally simulate an inguinal hernia. This layer, together with the infundibuliform fascia, is known as the *fascia propria of Cooper*, who described it as very strong in large, old herniæ. The parietal layer of the tunica vaginalis extends for half an inch above the level of the testis, forming a cul de sac at the beginning of the cord. Besides the (external) cremaster, two collections of unstriped muscle fibers are known as *cremaster muscles*, one of them in the cord (*internal cremaster*) the other in the subserous layer (*middle cremaster*). One muscular band of the latter, stronger than the rest, is said sometimes to groove a hydrocele, so as to partly divide it.

The two composite layers of the coverings of the testis have a separate blood supply, with *anastomoses* between the two layers and with the blood supply of the testis at the scrotal ligament and the base of the scrotum. The anastomosis between the two halves of the scrotum is quite free. The skin and dartos are supplied by the *pudic vessels* (external pudic and the superficial branch of the internal pudic), the envelopes of the testicle by the *cremasteric vessels*. Although the scrotum is very vascular its vitality is not great, so that it may slough from severe inflammation or pressure, hence *strapping*, if employed at all, should be applied with care, for it has been followed by

extensive sloughing. The large, superficial and often tortuous veins of the scrotum, which are visible through the skin, should be avoided in tapping a hydrocele. They end in the long saphenous vein, but communicate with the spermatic veins.

The *lymphatics* of the scrotum pass to the inner or middle group of the upper set of superficial inguinal lymph nodes. These nodes are involved in diseases of the testicle, as a rule, only when the scrotum is also involved. *Elephantiasis*, a disease marked by great hyperplasia of connective tissue and due to the irritation of filaria in the lymph vessels, occurs most frequently in the scrotum. The skin and dartos receive their *nerve supply* from the internal pudic and small sciatic nerves, etc.; the ilioinguinal does not supply the skin of the scrotum. *Embryologically* the scrotum, like the labia majora, is formed by the *genital ridge*, the two sides of which unite together mesially to form the scrotum. Failure of this union is one of the features of so-called hermaphroditism in certain of its forms. In these cases the ununited halves of the scrotum resemble the labia.

### The Testis.

**Position.**—(Fig. 97.) The testes are normally situated in the lower end of each half of the scrotal pouch where they are suspended by the spermatic cords at *unequal levels*, the left being commonly lower than the right, owing to the greater length of the left spermatic cord. This enables the testes to avoid pressure from one another. The testis is *held in position* and anchored to the postero-inferior part of the vaginal sac by the scrotal ligament, by its attachment to the infundibuliform fascia along the lower part of its posterior or straighter border, and by the reflection of the visceral layer of the tunica vaginalis to join the parietal layer postero-inferiorly. Hence when the vaginal sac is filled with fluid as in hydrocele or haematocele the testis occupies a *postero-inferior position* in the sac and we can safely puncture the sac in front or above. In about one case in twenty the testis is rotated on its vertical axis and attached antero-inferiorly (*inversion of the testis*) but in such a case we can still safely tap a hydrocele above and in front or at the side.

**Development and Descent.**—In early foetal life the testis is developed internal to the lower end of the kidney at the level of the second lumbar vertebra, hence the origin of the spermatic vessels in this region. It lies behind the peritoneum, or with a short mesentery of peritoneum (*mesorchium*), and to its lower end is attached a bundle of unstriped muscle fibers, the *gubernaculum testis* (rudder of the testis) whose three-tailed lower end is attached to the dartos at the bottom of the scrotum and to the two pillars of the external abdominal ring. Beginning to descend in the third month of fetal life it reaches the internal ring in the sixth month. Then, preceded by a pouch of peritoneum from this part (*processus vaginalis*), which pushes before it a sheath from each of the layers of the abdominal wall through which it passes, the testis reaches the external ring at the eighth month and

the bottom of the scrotum shortly before birth. Hence the presence of the testis in the scrotum is an indication of the maturity of a male fetus. The cause of this "descent of the testis" is uncertain, but it is probably partly due to the development of the pelvic and lumbar regions which grow upward away from the testis, anchored by the gubernaculum, and partly to the contraction or shortening of the latter, for the first cause would not take it beyond the internal ring at most.

The testis may be arrested in its descent in the abdomen, at the internal ring, in the inguinal canal or just outside of the latter. When the testes have not passed the external ring the condition is called *cryptorchism* (normal in certain animals, elephants, etc.) or *monocryptorchism* when only one testis is arrested. A testis arrested within the canal may, and one at the external ring usually does, reach the scrotum at or before puberty. A retained testis is *atrophic* and is said not to be functionally active; hence it may be removed without question in an operation when it complicates a hernia. It is also said to be especially liable to malignant disease, but the statement is supported by little proof. If it is lodged in the inguinal canal it may be mistaken for and *predisposes to a hernia* and is subject to attacks of inflammation from pressure or injury. Such an inflamed testis may cause errors in diagnosis, being mistaken for abscess, strangulated hernia, etc., unless it is noticed that the testis of that side is wanting in the scrotum. Again the testis may descend into the groin through the femoral instead of the inguinal canal, or it may wander into the perineum (*ectopion testis*).

The consistence of the testis is *firm* and *elastic*, more so when the tubules are full or in certain diseases, such as tuberculosis, syphilis or tumors, less so before puberty or when atrophy occurs from old age or otherwise. The consistence is normally *uniform* and the surface should be *smooth*, so that when nodules or localized hardening or softening occur the testis is abnormal or diseased. Partial induration of the epididymis indicates tuberculosis or a chronic following an acute inflammation (*epididymitis*), which is said to be nearly always in the tail of the organ.

The normal size (1½ inches in length, 1¼ inches in depth and a little less than 1 inch in thickness) and the normal weight (5 to 8 drachms) are not attained until after puberty, being much less before then. If there is only one testis (*monorchism*), or only one descended, its size and weight may be much increased, otherwise such increase indicates a pathological condition.

The great thickness (1 mm.) of its bluish-white fibrous covering, *tunica albuginea*, prevents any sudden expansion but allows a gradual increase in size, as in tumors or chronic inflammation. This accounts for the intense pain in acute orchitis, due to pressure on the nerves by the products of inflammation pent up within the unyielding capsule. If in such a case the inflammation is purulent and an opening occurs in the tunica albuginea the tension of the inflammatory products forces out the substance of the testis and we have *hernia testis* which may

even go on until all the testicular substance is extruded and only granulation tissue remains. This condition is therefore due to the firmness of the fibrous capsule. The pain of an epididymitis on the other hand is much less, as the fibrous covering of the epididymis is much less thick and firm and more elastic and yielding, so that this part may swell rapidly and extensively.

The chief relations of the testis are with its covering, the visceral layer of the tunica vaginalis, with the epididymis and with the cord. The testis is completely covered by the *visceral layer* of the *tunica vaginalis*, except along its posterior border, where superiorly the efferent tubules pass out into the head of the epididymis, below this the vessels enter and inferiorly the border is adherent to the infundibuliform fascia and attached to the scrotal ligament. Along this posterior border the visceral layer of the tunica vaginalis is continuous with the parietal layer either directly, as on the mesial side, or after partly covering the epididymis, as on the lateral side.

Normally the two serous layers are in contact, separated by only enough fluid to moisten or lubricate them. An increase of the amount of this fluid, which may reach several ounces or even pints, constitutes a *hydrocele* or, if the fluid is largely bloody, a *haematocele*. A hydrocele is *pear-shaped* with the small end above and is commonly *translucent*, except where the testis lies, the normal position of which we have seen above.

The upper tubular portion of the processus vaginalis usually atrophies soon after birth to a mere fibrous thread which lies among the elements of the spermatic cord and which we can sometimes trace from the bottom of the slight depression of the peritoneum at the internal ring to the upper end of the vaginal pouch. Sometimes however this upper tubular portion remains open (see p. 264), in whole or in part. If the entire "processus" remains open, fluid may pass into it from the peritoneum, or may be returned into the latter by pressure or posture. It would be unsafe to inject irritant fluids into such a congenital hydrocele, owing to its connection with the peritoneal cavity. If the processus is closed above and below, or at intervals, and is open between, fluid collecting in the unclosed portions above the vaginal pouch constitutes an *encysted hydrocele of the cord*, either monolocular or multilocular. Such hydroceles, like the processus vaginalis in which they are formed, lie in front of the cord, and the testis can be plainly felt below the swelling if there is no vaginal hydrocele as well. An *encysted hydrocele in the canal of Nuck*, which is occasionally met with, occurs in the similar process of peritoneum in the female.

The *epididymis* (Fig. 97) rests upon the posterior border and overlaps the back of the external surface of the testis. Its enlarged upper end or head, *globus major*, projects above the upper extremity of the testis, where it is readily *felt*. It is intimately *connected* with the upper end of the posterior border by the visceral layer of the tunica vaginalis, which covers it, and by the *vasa efferentia* which, coiled up as the *coni vasculosi*, form the great bulk of the *globus major*. Between the

body of the epididymis and the outer surface of the testis is a small fossa, the *digital fossa*, lined by the tunica vaginalis. On account of its *meso-epididymis*, connecting the body of the epididymis with the posterior border of the testis, the former is readily movable and may be pressed away from the testis and even more or less transversely placed, after stretching of this serous duplicature in cases of large hydrocele, etc.

The lower and somewhat enlarged end or *tail*, *globus minor*, reaches nearly to the lower limit of the posterior border of the testis, to which it is loosely connected. The *tunica vaginalis* leaves uncovered most of the tail, the posterior part of the inner surface of the body and the posterior border of the epididymis. Along the latter border and the mesial part of the posterior border of the testis the visceral is continuous with the parietal layer of the tunica vaginalis by means of two folds, between which the vessels pass to and enter the posterior borders of each organ. The *globus minor* is continuous with the *vas deferens*, hence inflammation reaching the epididymis along the *vas* should first affect this part. From its greater size when inflamed and swollen the *globus major* is much the most prominent part in epididymitis. Most of the cases of so-called swollen testis following a gonorrhoeal posterior urethritis, the passage of an instrument, etc., are really cases of *epididymitis*, the testis remaining unaffected. The hard and much enlarged epididymis can be felt behind, above and more or less external to the testis, which is normal in size and consistence. In *inversio testis* the relative positions of the parts enlarged are reversed. Tuberculosis commonly attacks primarily and often exclusively the epididymis, syphilis the testis.

**The arterial supply** of the testis is from the spermatic artery with some anastomotic supply from the artery of the *vas*. The veins enter the spermatic or pampiniform plexus. When varicosity of this plexus occurs before adolescence, or when it exists for a long time, it may cause atrophy of the testis. The elevation of the scrotum, practiced in all inflammations of the epididymis and the testis, acts by diminishing the congestion by favoring the venous but not the arterial circulation. The **lymphatics** enter the lumbar nodes. The rare instances where affections of the testis involve the inguinal nodes, without first involving the scrotal coverings, are to be explained by lymphatic anastomoses accompanying the vascular anastomoses which we know are present along the scrotal ligament, etc.

**The Nerve Supply.**—The association of the spermatic plexus, accompanying the spermatic artery and derived from the renal and aortic plexuses, with the abdominal sympathetic nerve centers explains (1) the pain in the testis during the passage of a renal calculus and (2) the nausea, faintness and collapse or syncope which result from a blow on the testis. The *pain* from such a blow extends into the loins, and pain in the back often follows the injection of a hydrocele or the dragging of a tumor of the testis. The sickening pain due to slight pressure on the testis is so characteristic as to be diagnostically useful in deter-

mining the presence or position of the testis in a swelling in the inguinal region or scrotum. Pressure on the *ovary* causes a somewhat similar pain.

**Fœtal Remains.**—Two structures go under the name of **hydatids of Morgagni**: (1) a pediculated, pear-shaped, serous sac filled with a clear fluid, attached to the *globus major* and not always present, and (2) a constantly present sessile, flattened and often lobulated structure, containing in its center a canal which may end blindly or in a *seminiferous canal*. The sessile hydatid is attached to the upper end of the testis, in front of the *globus major*, and represents the end of the duct of Müller; hence it is homologous with the fimbriated extremity of the Fallopian tube. The **paradidymis** or **organ of Giraldes** in adult life consists of a single tubule, probably derived from the Wolffian body, which is blind at both ends or connected at one end with the tube of the epididymis, or the *rete testis*. It appears as a yellowish-white patch, which lies outside of the parietal layer of the tunica vaginalis, on the lower part of the spermatic cord, in front of the spermatic plexus and posterior to the *globus major*.

The above fœtal remains, together with the *vas aberrans*, are of practical importance because they may give rise to *cystic tumors*, including the true *spermatic cysts* containing seminal fluid. The latter are most often formed from the tube of the epididymis, especially the *globus major*. The above cysts may project free into the cavity of the tunica vaginalis.

In addition to tuberculosis and syphilis the testis may be the seat of almost any *new growth* except lipoma. Sarcoma and chondroma are particularly common and tumors of the testis, like those of the parotid, are very liable to be "mixed," consisting of several kinds of new growth. New growths usually spring from the testis proper, seldom from the epididymis. Removal of the testes diminishes the size of the prostate, which is much atrophied in eunuchs; hence the employment of castration in the treatment of hypertrophy of the prostate, but the result appears to be only temporary. As division of the *vas deferens* causes atrophy of the testis it has also been employed for the same purpose.

The **spermatic cord** consists of (1) the *vas deferens*, (2) the artery of the *vas deferens*, (3) the *spermatic artery*, (4) sympathetic nerves accompanying the arteries, (5) the veins accompanying the two arteries, (6) lymphatics running with the veins, (7) the remains of the processus vaginalis, sometimes present and (8) the internal cremaster fibers of Henle (see p. 411). All these structures are joined together by a fatty connective tissue, continuous with the subperitoneal tissue, which may give origin to inguinal or scrotal *lipoma*, simulating true herniæ.

The *vas deferens* lies to the inner side and behind the epididymis at the commencement of the cord and bears the same relative position to the other elements of the cord above, where its hard *cord-like feeling* enables it to be readily found or avoided as occasion requires (see p. 378). In castration for tuberculosis or tumor of the testis, etc., it is

often advisable to remove the cord as high up as possible. The *two arteries* and their accompanying veins require ligation, and it is well to ligate them separately rather than to ligate the cord en masse.

The *cord* is covered by the same layers that envelop the testis, except the tunica vaginalis. Superiorly the *dartos* is replaced by superficial fascia, between which and the skin is a layer of subcutaneous connective tissue and fat. In reaching the cord, as in operations for varicocele, branches of the external pudic, cremasteric and superficial epigastric arteries are likely to be divided, and perhaps some branches of the superficial perineal arteries.

The *veins* of the *spermatic or pampiniform plexus* to the number of five or six lie in front of and surround the spermatic artery and present frequent anastomoses. They coalesce to three or four plexiform trunks in the inguinal canal, which unite into two and finally into a single vein accompanying the spermatic artery in the abdomen. The *frequency of varicosities of the spermatic veins, or varicocele, is explained by their length, dependent position, few and imperfect valves, lack of external support from the loose surrounding tissue, pressure in their passage through the inguinal canal, and their large size as compared with the arteries, which renders the blood current sluggish.* The aid furnished to many veins by muscular contraction is also wanting. Those with a normally active *dartos* seldom have varicocele. Several facts may be given to explain the greater frequency of varicocele on the left side, i. e., the greater length of the left spermatic cord, the pressure of the sigmoid colon, especially in cases of constipation, on the left spermatic vein, and the passage of the latter at a right angle into the renal vein, while the right vein enters the cava at an acute angle. Congenital defects of development may also help to explain the above features of varicocele, but this explanation is a supposition and needs explanation itself. Varicocele is especially an affection of early adult life and often spontaneously diminishes with the diminution of sexual vigor in old age. Of the two sets of veins it is the anterior set, or the spermatic plexus accompanying the spermatic artery, which is principally or solely involved.

In ligation or excision of these veins we must avoid the smaller set accompanying the *vas deferens*, which are sufficient to carry on the venous circulation. The *spermatic artery* need not be spared from among the veins, even if it can be, for the anastomoses with the artery of the *vas deferens* and the scrotal arteries are sufficient to supply the testis. It is important however to spare the *genitocrural nerve*, which supplies the *cremaster muscle*, for otherwise this muscle would be paralyzed and the testis would hang lower than before. At the internal abdominal ring the cord is formed by the coming together of the *vas deferens* and its vessels with the spermatic vessels.

### THE PERINEUM.

This corresponds to the outlet of the pelvis and includes the structures between the skin below and the pelvic floor above.

**Boundaries and Surface Landmarks.**—Its bony and fibrous boundaries form a *lozenge-shaped figure* with the symphysis in front, the coccyx behind and the ischiopubic rami, the ischial tuberosities and the great sacrosciatic ligaments on the sides. By deep pressure we can *feel* the bony landmarks and, in thin subjects, the sciatic ligaments, beneath the inner margins of the glutei maximi. In the erect position the *sciatic ligaments* are overlapped by the internal borders of the glutei maximi muscles, but not in the sitting or lithotomy position. The bony boundaries are seen to correspond with the pelvic outlet and hence vary in size in the two sexes (see p. 352). In the male the *transverse diameter* between the ischial tuberosities, usually  $3\frac{1}{2}$  inches, is sometimes so narrow (2 inches) as to interfere with lateral perineal incisions. The average *antero-posterior diameter* in the male is  $3\frac{1}{2}$  inches but, owing to the convexity of the parts, the surface measures 4 inches.

*Superficially* the male perineum is *limited* by the scrotum in front, the buttocks behind and the thighs laterally. With the thighs together and extended the perineum appears as a furrow between them, but with the thighs flexed and abducted (lithotomy position) the perineum appears as bounded above. The **median raphé** of the skin extends forward from the anus to the scrotum and thence onto the penis. As it represents the embryonic cutaneous seam of the two halves of the perineum *no vessels cross it*, hence it is chosen for *incisions* when possible. It is well to remember that it may be displaced to one side by adhesions.

The **depth** of the perineum, or the distance between the surface and the pelvic floor, *varies* individually with the amount of subcutaneous fat, and locally in the different parts of the area. Thus in the posterior and lateral parts it measures 2 to 3 inches, but less than 1 inch anteriorly. It is important to bear in mind this distance in operating on the pelvic viscera through the perineum, as in opening the bladder, etc. The **central tendinous point** of the perineum *lies* in the median line, midway between the center of the anus and the back of the scrotum, and 1 inch in front of the anus. It is the *meeting point* of the bulbo-cavernosus, superficial transversus perinei, sphincter ani and a few fibers of the levator ani muscles and the superficial and deep perineal fascia. As it corresponds to the center of the posterior edge of the deep perineal fascia (triangular ligament) the bulb and its artery are just in front of it. Hence in lithotomy and similar operations the *incision* should not commence much in front of this point. Corresponding to the bulb and the perineal portion of the corpus spongiosum, the *surface* is somewhat *elevated* in the median line in front of the central point, and this elevation may serve as a guide to the position of the bulb.

A nearly transverse line between the anterior part of the ischial tuberosities, which passes through the "central point," divides the region into an anterior or urethral triangle (perineum proper) and a posterior or anal triangle.

The "perineum proper" has the form of an equilateral triangle, measuring about  $3\frac{1}{2}$  inches on all sides. The base is not quite straight, but inclines forward from either side to the middle line, at the central point of the perineum. The skin is freely movable on the subjacent parts and is dark and thin, readily showing any extravasation of blood beneath it. The superficial layer of the superficial fascia contains little or no fat in the middle line but more fat laterally and posteriorly, where it is continuous with the subcutaneous fat of the thighs, of the ischio-rectal fossæ and of the buttocks. The superficial lymphatics run into the middle group of the superior inguinal nodes.

Apart from the preceding layers, the perineum proper consists of a triangular ledge of tissue, composed of three strong layers of fascia stretching nearly horizontally between the ischiopubic rami and enclosing two interfascial spaces. It is pierced by the urethra, and in the female, by the vagina.

The deep or membranous layer of the superficial fascia, the fascia of Colles or "perineal fascia," turns up behind the superficial transversus

FIG. 99.

Muscles of the male perineum. (GERRISH, after TESTUT.)

perinei muscle to join the base of the triangular ligament and thus helps to form the free posterior border of the "perineal ledge." It thus *shuts off* a *subfascial space* (the superficial perineal interspace) from the ischio-rectal fossa behind it. This space is separated from the thighs on either side by the attachment of the fascia to the ischiopubic rami, and from the pelvis by the attachment of the triangular ligament to

the same parts. Hence there is only one outlet for urine extravasated into this space, from rupture of the urethra contained within it, and that is forward to the scrotum and penis and thence, between the symphysis and the pubic spines, onto the abdomen beneath the deep layer of the superficial fascia, with which and the dartos of the scrotum this perineal fascia is continuous. (See pp. 240 and 410.) Extravasation of urine from rupture of the urethra is especially liable to occur in this space, beneath the perineal fascia. The products of inflammation and other fluid collections take the same course.

From the perineal fascia to the pelvic floor we find *alternate layers of fascia and muscle*, etc. Thus in the *subfascial space*, beneath the perineal fascia and superficial to the triangular ligament, we find the root of the penis and its muscles, vessels and nerves, together with the superficial transversus perinei muscles and their vessels and nerves. The latter muscles lying along the posterior boundary or base of this region, together with their accompanying vessels and nerves, serve as landmarks and are liable to be cut into or across in lateral incisions, as in lateral lithotomy. They may be cut with impunity. Forming the root of the penis we find laterally the crura penis covered by the ischiocavernosi muscles and attached to the ischiopubic rami, and mesially the bulb covered by the bulbocavernosus. The space is divided by the bulbocavernosus into two lateral muscular triangles, bounded laterally by the erectors penis, covering the crura penis, and posteriorly by the two superficial transversus perinei muscles. Sometimes these muscles cover, or nearly cover, the entire area and again they may leave a considerable gap between them, showing the next deeper layer, the triangular ligament, which forms the roof (often called the floor) of this space.

The **triangular ligament** measures about an inch and a half from the subpubic ligament to the middle of its base, at the central point of the perineum. Its principal *function* is to support the urethra in its course beneath the symphysis. Along its base its two layers fuse with one another and with the perineal fascia and thereby inclose the perineal interspaces posteriorly, and form the free border of the perineal ledge. This border is incised in lateral and median lithotomy and in the perineal operations on the urethra, bladder, prostate, etc. The two layers of the triangular ligament separate from one another anteriorly to inclose the wedge-shaped deep perineal interspace.

The *superficial layer of the triangular ligament* is pierced by the *urethra* about an inch behind the symphysis, and around this opening are closely attached the bulb of the urethra and its sheath, while the *artery of the bulb* pierces it on either side of the urethral opening. It is also pierced by the *ducts of Cowper's glands* on each side of and somewhat behind the urethral aperture, and by the *vessels of the corpora cavernosa* more anteriorly and close to the lateral attachment of the ligament. *Anteriorly a small gap* is left between this layer and the subpubic ligament through which the dorsal vessels and nerves of the penis pass from the deep to the superficial perineal interspace. The

anterior part of this layer, forming the posterior boundary of the aperture for the dorsal vessels, etc., is somewhat thickened and is sometimes called the preurethral ligament (Joessel, Waldeyer). Laterally this layer is firmly attached to the ischiopubic rami, above the attachment of the perineal fascia.

FIG. 100.

Deep layer of muscles of the male perineum. On the left side of the subject the superficial layer of the triangular ligament has been removed, on the right side it is in place over the compressor urethræ or deep transversus perinei muscle. The central part of the levator ani is removed, exposing the prostate, etc. (TESTUT.)

The **deep perineal interspace**, between the two layers of the triangular ligament, is *wedge-shaped* with the apex behind, where the two layers come together. It contains the membranous urethra (see p. 399), Cowper's glands (see p. 399), the deep transversus perinei or compressor urethræ muscle, the internal pudic vessels, nerves and lymphatics with their terminal and deep branches (*i. e.*, to the bulb, the corpora cavernosa and the dorsum of the penis). The **deep transversus perinei** or **compressor urethræ** muscle is a voluntary muscle whose inner circular fibers surround the membranous urethra and are continuous with the voluntary fibers in front of the prostatic urethra. The greater part of its fibers pass transversely and join an indistinct median raphé, while a few run obliquely and sagittally. They compress and help to expel the contents of the membranous urethra and of Cowper's glands, as in emission, they serve as the external sphincter vesicæ and assist in the erection of the penis by compression of the veins from the bulb, the corpora cavernosa and the dorsum of the

penis, which pass through it. Some of its fibers are cut in lateral lithotomy and, to a less extent, in many median perineal operations.

The artery of the bulb runs inward in this interspace about half an inch, sometimes less, in front of the base of the ligament or  $1\frac{1}{2}$  to  $1\frac{1}{4}$  inches in front of the anus. Hence the incision in lateral lithotomy, etc., should not be commenced more than  $1\frac{1}{4}$  inches in front of the anus.

The superior or deep layer of the triangular ligament is continuous with the obturator fascia along the upper lip of the inner edge of the ischiopubic rami, where both these fasciae are attached. It joins the superficial layer anteriorly, at the preurethral ligament, and posteriorly along the posterior edge of the perineal ledge. Superiorly it forms the floor of the anterior recess of the ischiorectal fossa, on either side of the prostate. The apex of the prostate rests upon it mesially, and its fibrous capsule, derived from the rectovesical fascia, fuses with it. The dorsal vein passes between it and the subpubic ligament, the pudic vessels and nerves pierce it. Incision through the posterior part of this layer on either side opens the anterior recess of the ischiorectal fossa, and then, being continued more deeply, cuts the levator ani with the anal fascia below and the rectovesical fascia above it, and thus enters the pelvic cavity. Median incision through this layer involves the prostate above it.

In lateral lithotomy the 2 to 3 inch incision, commenced about  $1\frac{1}{4}$  inches in front of the anus and a little to the left of the median line (to avoid the bulb and its artery), is carried backward and outward to a point somewhat behind and external to the mid-point between the anus and the ischial tuberosity. Through the anterior and deeper part of the incision the knife is carried into the membranous urethra and, along the staff, through this and the prostate into the bladder. The prostate is divided obliquely backwards and outwards. We divide the skin; the superficial fasciae; the transversus perinei muscle, vessels and nerve; the external hemorrhoidal vessels and nerves; the base of the triangular ligament and compressor urethrae muscle; the membranous and prostatic urethrae; the anterior fibers of the levator ani; and the left lateral lobe of the prostate.

**Parts to be Avoided.**—We avoid wounding the *bulb* by commencing the incision to one side of the median line and by drawing the staff, and with it the bulb, well forward under the pubes. The *artery of the bulb* is avoided by commencing the incision not more than  $1\frac{1}{4}$  inches in front of the anus. The *rectum* is easily avoidable if it is not distended and if the posterior part of the incision is not carried too far back or too near the median line. On the other hand the *pudic vessels* may possibly, though not probably, be wounded if the incision is carried far to the side. If the *incision in the prostate* passes beyond the prostatic capsule, so as to incise the rectovesical fascia, it lays open the subperitoneal tissue of the pelvic cavity, the ischiorectal fossa and the neck of the bladder into one large space. This is most likely to occur in incising the vesical outlet, for the incision into the lower end of the gland is below the reflection of the rectovesical fascia from the

pelvic floor onto the prostate. If the *prostatic incision* is too vertical the left ejaculatory duct is in danger of being incised. The prostatic venous plexus cannot escape. When the *accessory pudic artery* is present, it is likely to be injured as it passes forward beneath the sides of the prostate. In children lateral lithotomy or any form of perineal approach to the bladder is more difficult and objectionable, because the pelvis, pelvic outlet and perineum are narrow; the bladder is higher up, more movable and less strongly attached, and the prostate is rudimentary, so that more of the vesical outlet itself has to be cut, while the peritoneal pouch descends lower and may be wounded. The suprapubic route, on the other hand, is easier on account of the high position of the bladder, so that it is to be preferred.

In *median lithotomy* or *cystotomy*, or the similar incision in external urethrotomy, perineal section, etc., the *parts divided* are (1) the skin in the median raphé in front of the anus for  $1\frac{1}{2}$  inches, (2) superficial fascia, (3) sphincter ani, (4) the central point of the perineum, (5) the base of the triangular ligament and of (6) the compressor urethræ muscle, (7) the membranous urethra. One finger in the rectum to guide the upwardly directed knife diminishes the risk of wounding the gut. There is less cutting and more dilating in median cystotomy, for the prostatic urethra and vesical outlet are only dilated and not cut. The *advantages* of the median operation consist in (1) little bleeding, owing to the slight vascularity of the raphé and median line of the perineum, and (2) little danger of wounding the pelvic fascia, for the prostate and vesical outlet are stretched and not cut. It is an excellent operation for the extraction of small stones. On the other hand it possesses *disadvantages* in (1) the danger of wounding the bulb, which, however, does not bleed much if incised in the exact median line, and (2) the little space obtained for the extraction of a stone. Moreover in children it is *contraindicated*, for, owing to the small size of the prostate and vesical outlet and the slight attachments of these parts, the bladder may be torn from the urethra in reaching it with the finger.

When we wish to expose the prostate or seminal vesicles other perineal incisions are useful, such as the *curved transverse incision* of Zuckerkandl, and the *median incision encircling the anus* on one side, as in v. Dittel's lateral prostatectomy. The greater part of these incisions is in the ischiorectal region. They aim to expose the prostate after dividing the anterior fibers of the levator ani muscle. Then the seminal vesicles may be exposed by separating the rectum from the prostate and bladder. Zuckerkandl's curved incision is concave toward the rectum. In all perineal operations on the male bladder it should be remembered that the vesical outlet lies  $2\frac{1}{2}$  to 3 inches from the surface, in the lithotomy position. But this distance may be so increased in some cases of prostatic hypertrophy as to make the perineal route to the bladder difficult or even contraindicated.

The **perineum in the female** differs from that in the male in the perforation of all the layers in the median line by the vulvovaginal passage and the resulting necessary adaptation of the muscles. It is

as if the bulbocavernosi and the bulb were cleft in two halves through their median raphé. The median cleft thus formed represents the vulva and the lower end of the vagina, while the two halves of the bulb and of the bulbocavernosi represent the bulbi vestibuli and the attenuated compressor or sphincter vaginæ respectively. The corpora cavernosa, the ischiocavernosi and the superficial transverse perinei muscles differ only in their smaller size. The deep transversus perinei muscle, like the two layers of the triangular ligament, is of course partly cleft by the vagina.

The "perineal body," *triangular* on sagittal section and *bounded* in front by the vulvovaginal wall, behind by the anterior rectal wall and below by the cutaneous surface between the anus and the posterior vulvar commissure, is peculiar to the female. Besides the central point of the perineum and the muscles that meet here it contains a meshwork of connective, elastic and unstriped muscle tissue. Thus it is fitted to stretch in parturition as it does to a remarkable degree during the passage of the head. It is in this part that ruptures of the perineum occur during labor. Such ruptures may be superficial or they may even extend entirely through into the rectum. It is the ischiorectal regions and the portion of the perineum behind the vulva, not the firmer anterior part, that yield most in parturition so as to allow the passage of the foetal head. The cutaneous base of the perineal body, between the anal and vaginal orifices, is often spoken of as the "perineum." It measures  $1\frac{1}{2}$  inches from back to front and extends laterally between the two ischial tuberosities.

### The Anal Triangle or Ischiorectal Region.

The *superficial fascia* contains a great abundance of *fat* which fills the two pyramidal *ischiorectal fossæ*, lying one on either side of the anus. (Fig. 107.) These fossæ are *bounded* above and internally by the obliquely directed levator ani and coccygeus muscles (pelvic floor), lined beneath by the ischiorectal or anal fascia, and externally by the vertical obturator internus, covered by the obturator fascia. In front each fossa ends superficially at the base of the perineal ledge, but more deeply it extends forward, nearly as far as the symphysis, as the *anterior recess*. This lies on top of the perineal ledge, beneath the levator ani, and extends forward on either side of the prostate, between it and the ischiopubic rami laterally. Posteriorly each fossa ends superficially along the great sacrosciatic ligament, but deeply it extends backward a variable distance toward the sacrum between the ligament and the pelvic floor, as the *posterior recess*.

The *apex* of the fossa is along the white line on the obturator fascia, or a little below it, so that its *depth* is about two inches behind, less in front. The *base* measures an inch in breadth and two inches from before backward. *Crossing* this space about its center, from the lateral wall to the anus, are the *external hemorrhoidal vessels*, while the external angle is crossed by the *superficial perineal vessels and nerves* and along the posterior border runs the *fourth sacral nerve*. The presence

## PLATE XLIX.

FIG. 101.

Frontal section of the ischiorectal space, passing through the ischial tuberosities. (Tillaux.)

of these nerves, especially the hemorrhoidal, explains the great *pain* which usually accompanies **ischiorectal abscess**. In *opening* an ischio-rectal abscess the structures to *avoid* are the pudic and external hemorrhoidal vessels and the rectum. We *incise* in a line radiating from the anus, being careful not to incise too deeply near the anus, on account of the rectum, or too far toward the tuber ischii, where the pudic vessels run in a canal (Alcock's) in the obturator fascia, 1 to  $1\frac{1}{2}$  inches above the lower end of the tuberosity. Early incision should be practiced to prevent the inflammation from extending throughout the entire fossa.

*Inflammation* in the ischiorectal fossa is *favored* by the poor blood supply of the contained fat and by the tendency to congestion, due to the dependent position and lack of support of the veins, especially in patients suffering from venous congestion or feeble circulation, such as occurs in diseases of the liver (cirrhosis), heart and lungs (phthisis). The inflammation is also favored by sitting on a cold, wet seat, by injury and by the passage of infection through the rectal wall, preceded perhaps by an ulcer of the lower rectum. *Ischiorectal abscess bulges and tends to break* where resistance is least, *i. e.*, in the rectum or on the skin beside the anus or along the border of the gluteus maximus. If it perforates both on the skin and in the rectum a complete **fistula in ano** results, whose *internal opening* is usually within half an inch of the anus. Owing to the constant dragging apart of the walls, toward the anus by the sphincter and from the anus by the levator ani, and the reinfection of the tract from the rectum spontaneous cure is rare and operation is required (see also p. 364).

The pad of fat filling the ischiorectal fossa serves as an elastic cushion to the rectum and allows its descent and expansion during defecation. The anal portion of the rectum occupies the space between these two fossæ. The ischiorectal fossa is opened into in lateral lithotomy and in the lateral and transversely curved incisions to explore the prostate, seminal vesicles, etc.

## CHAPTER VI.

### THE LOWER EXTREMITY.

THE lower extremity is especially *adapted to bear the weight of the body* by its stronger and heavier build and the stronger and less movable connection of its first segment, the thigh, as compared with the upper extremity.

#### THE HIP.

The upper segment, the region of the hip, will be studied in *two sections*, (1) a posterior or gluteal region, the buttocks, and (2) an anterior region including the hip joint.

#### The Posterior or Gluteal Region, the Buttocks.

This region is *bounded* above by the iliac crest, below by the gluteal fold, internally by the sacrum and coccyx and externally by a line from the anterior superior iliac spine to the great trochanter.

**Surface Markings and Landmarks.**—The iliac crest and its anterior superior spine are readily felt. The *posterior superior spine* is less distinct, especially in stout subjects, in whom its position is indicated by a small depression. The *great trochanter* is a prominent landmark, especially when the thigh is adducted or rotated out. In very stout subjects a slight depression marks its position. Its upper border is made less sharply defined by the tendon of the gluteus medius which passes over it. The *ischial tuberosities* are readily felt on the borderline between the buttocks and the perineum. When the thighs are extended they are covered by the fleshy fibers of the lower borders of the glutei maximi, which rise above them when the thighs are flexed. The *sciatic notch* can only be felt in those greatly emaciated. The transverse gluteal fold, or “*fold of the buttocks*,” is neither due to nor does it correspond with the lower border of the gluteus maximus, which is lower and more oblique than the fold. The fold is *due to* a creasing of the skin in extension of the hip. In *flexion* of the hip joint the buttocks are flattened and the *fold becomes oblique* and is finally *obliterated*. Its disappearance in early hip disease is a useful diagnostic sign and is due to the flexion of the hip joint which is almost constantly present. The change in the fold and the flattening of the buttocks are not due to but precede the wasting of the gluteal muscles, which exaggerates these symptoms. The *great sacro-sciatic ligament* can be felt on deep pressure beneath the lower edge of the gluteus maximus. The *tensor vaginalis femoris* forms a slight prominence extending from a point just outside the anterior superior spine downward and somewhat backward to the outer aspect of the thigh three to four inches below the great trochanter.

**Topography.**—The *posterior superior iliac spine* is on a level with the second sacral spine and the center of the sacro-iliac joint. In this connection it may be noted that the *lowest limit of the spinal membranes* and the cerebrospinal fluid corresponds to the third sacral spine and the upper border of the great sacro-sciatic notch. The *spine of the ischium* is on a level with the first piece of the coccyx. The level of the *upper border of the great trochanter* is about  $\frac{3}{4}$  of an inch below the top of the femoral head, at or just below the center of the hip joint, and nearly on a level with the pubic spine. The atrophy of the gluteus medius and minimus muscles, which fill up the hollow between the ilium and the trochanter and render the prominence of the latter comparatively slight, makes the trochanter very conspicuous.

**Nelaton's line**, which is drawn from the anterior superior iliac spine to the most prominent part of the tuber ischii, normally touches the top of the great trochanter and crosses the center of the acetabulum. Its relation to the trochanter is used in the diagnosis of fractures of the neck of the femur, dislocations of the hip and late stages of hip joint disease, in which the trochanter is displaced upward. A still more convenient line for this purpose is **Bryant's line**, the upper line of Bryant's triangle. This line is drawn vertically backward (in the horizontal posture) from the anterior superior iliac spine, and the distance from this line to the top of the great trochanter, as compared with that on the opposite side, indicates any displacement upward of the trochanter.

**Position of the Vessels and Nerves.**—The *gluteal artery and the nerve* just below it, as they emerge from the pelvis, correspond about to the middle of the *superior border of the sciatic notch*. This point is indicated by the junction of the upper and middle thirds of a *line* drawn from the posterior superior iliac spine to the top of the great trochanter, when the thigh is slightly flexed and rotated inward. Incising in this line, and splitting the gluteus maximus muscle, the top of the sciatic notch is felt for and the vessel is there found, if its ligature is required. The *sciatic artery*, with the *great sciatic nerve* external to it, *emerges* from the sciatic notch at a point corresponding to the junction of the middle and lower thirds of a *line* drawn from the posterior superior iliac spine to the outer part of the tuber ischii. This line crosses the *posterior inferior iliac spine* two inches below the upper end and the *ischial spine* four inches below. The latter spine is crossed by the internal pudic artery as it passes from the great to the small sacro-sciatic foramen.

The **great sciatic nerve**, emerging from the pelvis at the point mentioned, *passes* thence down the middle of the back of the thigh *in a line* to the middle of the popliteal space, and *crosses the line* from the tuber ischii to the outer side of the great trochanter at the junction of its middle and inner thirds. At this point the nerve emerges from beneath the lower border of the gluteus maximus and is *most accessible*, being only covered by the skin and fascia, before it is crossed by the long head of the biceps. It may be *exposed* by an incision having this

point as its center and running either in the line of the nerve or along the lower border of the gluteus maximus, across this line. The latter muscle is retracted laterally and the nerve is found as a white cord in the loose tissue separating this muscle from the hamstring muscles.

We may now study this region by layers. The skin is thick and firmly connected with the underlying fascia, so that it is *not movable*. It is often the seat of furuncles, which are very painful, for its *sensitivity*, derived from a number of nerves,<sup>1</sup> is almost as acute as that over the dorsum of the hand. The subcutaneous tissue contains a large amount of *fat*, to which, even more than to the development of the gluteus maximus, the buttocks owe their prominence and roundness. This tissue is a *favorite site for lipomata* and its laxity allows large effusions of pus and blood to occur.

The deep fascia is attached to the iliac crest above and the sacrum and coccyx behind, and splits to inclose the gluteus maximus in a sheath. The deep layer of this sheath covers the gluteus medius, over which the fascia is thicker than over the maximus, especially in front of the latter. The glutei medius and minimus are enclosed by means of this fascia in an *osseo-aponeurotic space*, which is only open below toward the thigh and internally at the sciatic foramina. *Effusions* of blood or pus pent up in this space press upon the contained nerves and explain the severe pains associated with them. Such abscesses may extend into the pelvis or a pelvic abscess may extend into this space, through the sacral foramina. Pus or blood beneath the deep fascia often travels for some distance down the thigh before it can reach the surface, and in one case, related by Farabeuf, the abscess reached the ankle before it broke. *Extravasations of blood* beneath the fascia may fluctuate and be mistaken for abscess, as they may occur without any discoloration of the skin, at least for some time, and then perhaps at some distance down the thigh. The deep or *gluteal fascia* is continuous below with the fascia lata of the thigh, and laterally with that thickened part of it known, from its attachments, as the *iliotibial band*. The latter serves as the insertion of the tensor vaginæ femoris and the anterior expanded part of the gluteus maximus tendon, both of which increase the thickness of the band. Across the gap between the iliac crest and the great trochanter this band is tightly stretched, so as to firmly resist the pressure of the fingers. If, however, the trochanter is raised this band is relaxed, a fact that may be useful in the diagnosis of fractures of the neck of the femur, etc.

The muscles of the buttocks may be divided into *three layers*, between the outer of which, consisting of the gluteus maximus, and the middle, comprising the gluteus medius, pyriformis, obturator internus and quadratus, lie most of the important nerves and vessels. Most *incisions* in this region are made parallel with the fibers of the gluteus maximus, which run obliquely downward and forward. The muscle

<sup>1</sup> These include filaments of the posterior branches of the lumbar nerves, some branches of the sacral nerves, the lateral cutaneous branch of the last thoracic nerve, the iliac branch of the iliohypogastric nerve, large branches of the small sciatic nerve and filaments of the external cutaneous nerve.

PLATE L.

FIG. 102.

Gluteal region of left side after removal of the gluteus maximus and part of the gluteus medius. (Joessel.)

may then be split instead of cut. The *gluteus maximus* does not act to maintain the erect position, but only in rising to that position, in climbing stairs, etc., in jumping, and in carrying heavy weights on the back. Hence when this muscle is paralyzed the patient can walk on a level surface, but has difficulty in rising from a seat, in climbing stairs, etc. In paralysis of the *gluteus medius* there is difficulty in maintaining the erect position on the side paralyzed.

Of the bursæ in this region, three at least are over the greater trochanter, separating the latter from each of the three gluteal muscles. Only that between the trochanter and the *gluteus maximus* is of much practical importance for it may be inflamed and render painful the movements of the thigh. Hence in the inflammation of this bursa, the thigh is kept flexed and adducted, to rest the muscle whose action is to extend and abduct it. A bursa over the tuber ischii separates that process from the skin and subcutaneous tissues, in the sitting posture. (See pp. 345 and 426.) Among those whose occupation requires much sitting this bursa is often inflamed and, when inflamed, it is known, according to circumstances, as "weaver's," "coachman's," "draymen's," or "lighterman's" bursa. When enlarged it may press upon the inferior pudendal nerve.

**Vessels.**—The *gluteal artery* is usually the largest of this region, being of the size of the ulnar, hence its wounds are serious and have been rapidly fatal. Wounds of this artery usually involve only its branches, for the portion of its trunk outside of the pelvis is not longer than 5 mm. (Bouisson). Hence in place of extra-pelvic ligature of the vessel for aneurism, ligation of the internal iliac artery is usually performed. *Gluteal aneurism* is not very uncommon and compression of the internal iliac artery, through the rectum, has been tried by Dr. Sands (Am. Jour. Med. Sci., 1881), but not effectively. If the aneurism involves the trunk of the gluteal artery, which runs, near its commencement, between the lumbosacral cord and the first sacral nerve, nerve symptoms from pressure can hardly fail to occur. The *gluteal and sciatic arteries* can be and have been ligated for wounds, through an incision in the buttocks over their course. (See p. 427.) The size of the accompanying veins and their close attachment to the artery increase the difficulty of ligation of the gluteal artery. There are several cases known, of which Henle collected six, where the greatly enlarged *sciatic artery*, running alongside of the sciatic nerve, took the place of the femoral to the popliteal space, in the absence of the femoral artery. The sciatic artery is most important in the *collateral circulation* after ligation of the femoral.

The superficial lymphatics of the buttocks run to the inguinal nodes, the deep lymphatics accompany the blood vessels to the nodes lying near the pyriformis, and thence to the internal iliac nodes.

**The great sciatic nerve**, after emerging from the pelvis at the point indicated above, is covered by the *gluteus maximus* and lies upon the *obturator internus* and the *quadratus femoris*. Neuralgia in this nerve is known as *sciatica*, a condition due to a variety of causes. Within the

*pelvis* aneurism of some of the branches of the internal iliac artery, engorgement of some of the pelvic veins lying in front of it (Erb), fecal accumulation in the rectum, the foetal head in tedious labors and various forms of pelvic tumor may cause sciatica by pressure. I have lately seen two cases where a tumor of the postero-lateral wall of the pelvis, palpable through the rectum, caused severe sciatica. *Outside of the pelvis* it is near enough to the surface to be affected by cold.

Stretching the nerve has been employed in the treatment of this condition. The so-called bloodless or *dry stretching* consists in forcibly flexing the hip while the knee is kept extended. But this stretches not only the nerve, but also the hamstring muscles, hence *wet stretching* is usually employed, the nerve being first exposed by an incision (see p. 427-8). Trombetta found that a weight of 183 pounds was required to break the great sciatic nerve, representing a force not likely to be equalled in stretching. But the nerve can be torn away from the soft spinal cord by a force not at all sufficient to rupture the nerve, hence care must be exercised in making traction on its proximal side.

The possibility of wounding the pelvic viscera through the sciatic foramina, in wounds of the buttocks, should be remembered. Treves mentions a case of a fatal stab wound of the bladder through the buttock and the rectum has been injured in like manner. We operate upon the pelvic viscera through the great sacrosciatic foramen after division of the great sacrosciatic ligament, with or without removal of the coccyx and part of the sacrum. The former is the method of Kraske in resection of the rectum.

#### The Anterior or Subinguinal Region, the Region of Scarpa's Triangle.

This is bounded above by Poupart's ligament, below by a line 12 to 15 cm. below it, on a level with the gluteal fold.

**Surface Markings and Landmarks.**—The anterior superior iliac spine, the pubic spine and Poupart's ligament are most important landmarks and readily made out (see p. 237-8). The *sartorius muscle* is rendered visible or palpable when the thigh is raised and adducted, the *adductor longus* when it is adducted in spite of resistance. The former runs obliquely downward and inward from the anterior superior iliac spine, the latter downward and outward from just below the pubic spine, hence it may be used as a guide to that spine in stout females. These two muscles, crossing 12 to 15 cm. below Poupart's ligament (10 cm. in muscular subjects), bound, with the latter, Scarpa's triangle. This triangle may appear as a slight hollow below the fold of the groin. In thin subjects the lower group (saphenous) of superficial lymph nodes can be felt near the base of the triangle; if enlarged they are readily felt. In emaciated subjects a prominence sometimes appears below the outer half of Poupart's ligament, corresponding to the *head of the femur*, which may be indistinctly felt in extension and rotation outward of the thigh.

**Topography.**—The *femoral ring* lies on the horizontal line connecting the pubic spine and the top of the great trochanter, one inch from the former. It is also half an inch internal to the femoral artery just below Poupart's ligament. The *artery* is a little internal to the middle of the ligament, or midway between the anterior superior iliac spine and the symphysis. From thence the *line of the artery* is drawn to the adductor tubercle, or the back of the inner condyle, the thigh being slightly flexed and abducted. The upper two thirds of this line corresponds to the position of the femoral artery. Its *profunda branch* is given off about  $1\frac{1}{2}$  inches below Poupart's ligament and the artery is covered by the sartorius about three to four inches below the same point. The *femoral vein* in all parts of its course bears a relation to the artery just the reverse of the sartorius muscle. The *saphenous opening* lies with its center  $1\frac{1}{2}$  inches below and also external to the pubic spine, where its position is sometimes indicated by a slight depression. In those without much subcutaneous fat the *long saphenous vein* can be seen or felt running up to the saphenous opening. This vein penetrates the cribiform fascia to join the femoral vein three to four cm. below Poupart's ligament. Just below its passage through the fascia it sometimes presents a dilatation, which might even be mistaken for a femoral hernia. This vein and its tributaries are often the seat of varices, commonly the result of congenital conditions.

The *skin* is *thin* and, below Poupart's ligament, very *movable* on account of its loose attachment. *Incisions* parallel with Poupart's ligament do not gape, hence in opening abscesses here a vertical incision affords better drainage by allowing separation of the edges. After burns and other loss of substance of the skin of this region the resulting cicatrix may cause flexion of the hip by *cicatricial contraction*. *Supernumerary mammary glands* are sometimes found in this region and Treves refers to a case, related by Jessieu, of a woman who nursed her child from a breast so placed.

The *superficial fascia* is usually described in *two layers*, of which the superficial one contains the subcutaneous fat, which may be so thick as to make operations here more difficult. This tissue is a *favorite situation for fatty tumors* which here show a tendency to travel in the direction of gravity, owing to the looseness of the tissue and of the capsule of the tumor. Between the two layers are the lower or vertical group of superficial inguinal nodes (*saphenous nodes*) which receive lymphatics from the surface of the lower extremity, the perineum and scrotum and sometimes from the penis, vulva, urethra and the lower part of the vagina. They lie over the saphenous opening. When these glands are enlarged or the seat of abscess, as often occurs, we should look to the parts named for the primary lesion.

The *cribriform fascia* is variously described. English and American authors, for the most part, consider it as belonging to the *deep layer of the superficial fascia* and as covering an oval notch which is supposed to intervene between the anterior or iliac portion and the deeper

or pectineal portion of the fascia lata. German and French authors consider it as a *part of the deep fascia* (fascia lata) which divides below Poupart's ligament into two triangular layers, one of which passes in front and the other behind the femoral vessels to unite together externally in front of the iliopsoas, internally in front of the pectineus and below around the sheath of the vessels, 3 cm. below Poupart's ligament. In either case the eribriform fascia refers to the fascia covering an oval area, the *saphenous opening*, measuring one inch in its long or vertical diameter. This fascia is thin and perforated by lymphatic vessels, passing from the superficial to the deep nodes, and, at its lower end, by the long saphenous vein as it passes back to empty into the femoral vein. The perforations give rise to the name eribriform (sieve-like). The femoral canal and the vascular and muscular compartments have been already referred to (see pp. 269-70). The firm *deep fascia* (fascia lata) affects the extension of underlying growths and abscesses and the opening of the latter. If a psoas abscess breaks through the sheath of the iliopsoas below Poupart's ligament it may travel in the line of gravity far down the thigh before it opens on the surface.

Within Scarpa's triangle, and at a deeper level, is a *second triangle* or a groove between the iliopsoas and the pectineus (*fossa iliopectinea*), in which lie the femoral vessels. The iliopsoas and a layer of fatty and areolar tissue intervenes between the vessels and the hip joint, so that in amputation or excision at the hip joint the vessels are protected from injury, in freeing the head of the bone. Between the iliopsoas and the thinnest part of the capsule of the hip is a *bursa* which may communicate with the joint. This bursa may form a large tumor in this region when chronically inflamed. Inflammation of this bursa may extend to the hip joint or vice versa. *Sprain* or even partial rupture of the *adductor group of muscles*, especially the adductor longus, often occurs in horseback exercise. The lesion is usually close to their pelvic attachments. It may be accompanied by much effusion of blood, and may be followed by the ossification of the tendon of the adductor longus or magnus, to the extent of  $\frac{1}{2}$  to 3 inches, a condition known as *rider's bone*.

**Vessels.**—The *femoral artery* bisects Scarpa's triangle from its base to its apex. The line of its course has already been given. *Where it crosses the pelvic margin*, just below Poupart's ligament and  $3\frac{1}{2}$  cm. external to the pubic spine (Richet), it is only separated from the iliopectineal eminence by a thin layer of the iliopsoas. Hence compression of the vessel is here most easily made by pressure backward. *A little lower* it lies in front of the head of the femur, from which it is separated by a thicker layer of the iliopsoas. *Still lower* it lies in front of and internal to the neck of the femur and the hip capsule. *In applying pressure* to the artery we should avoid pressure on the vein because of the possible danger of phlebitis. The *anterior crural nerve* is separated from the artery by the iliae fascia, so that, although it lies only one fourth inch external to it just below Poupart's ligament, it is not in danger of injury by pressure in compression of the artery.

PLATE LI.

FIG. 103.

### Region of Scarpa's triangle, left side. (Joessel.)

*The length of the common femoral artery*, or that part above the profunda, may practically be taken to be the distance between the origin of the deep epigastric and the profunda femoris. Although this is about four cm. in the majority of cases, Vignerie found that in about sixteen per cent. the distance was two cm. or less. The common femoral may therefore be so short as to render ligature difficult. Before the days of antisepsis and asepsis the nearness of a large collateral branch was most important in the ligature of large arteries, on account of the danger of secondary hemorrhage, so that it was advised to tie the external iliac instead of the common femoral, where ligature of the latter was indicated. Nowadays a long clot, or indeed any clot, between the point of ligature and the nearest large branch is not considered necessary, so that this objection to tying the common femoral no longer holds good. However the *femoral is commonly ligated at the apex of Scarpa's triangle*, unless ligature at this point is contraindicated. Here the sartorius crossing it serves as a guide; the vein is behind and somewhat adherent, the saphenous vein is internal and the long saphenous nerve is external. The femoral artery, from its superficial position in Scarpa's triangle, is *liable to be wounded*. Aneurism is *common in the common femoral*, for the artery is affected by the movements of the hip, is exposed to injury from its superficial position and it bifurcates into two large trunks. Arterio-venous aneurisms from wounds may also occur here.

As the *tributaries of the common femoral vein*, or that portion of the femoral vein above the entrance of the long saphenous vein, are provided with valves which should normally prevent the backward flow from the femoral to the tributaries of the pelvic veins anastomosing with them, it would appear as if the femoral vein was the only outlet to the pelvis of the blood of the lower extremity. From this premise it was argued that the ligature of the common femoral vein alone would lead to gangrene, and should not be done without simultaneous ligature of the artery, to prevent the inflow of too much blood into the limb. In fact many ligated the artery only in case of a wound of the vein. But many cases of isolated ligature of the common femoral vein are on record without gangrene resulting. In fact Braun found from statistics that the ligature of the common femoral vein alone was less often followed by gangrene of the extremity than either ligature of the artery alone or of both artery and vein. Experimentally Braun found that in 85 per cent. the valves of the anastomosing tributaries gave way before a pressure of 180 mm. of mercury. The greater the pressure the better the chance of venous collateral circulation, hence the artery should not be ligated, unless necessary, in order to increase the pressure in the veins. According to Richet and Verneuil the collateral circulation occurs especially between the external pudic veins and the veins of the pelvis and between the internal circumflex veins and the veins of the buttocks. It is quite probable that there are more collateral anastomoses than are known and that the valves are often wanting or insufficient.

*Phlebitis* involves the femoral vein not infrequently as a sequela of typhoid and other fevers, as well as of operations like appendectomy, hysterectomy, etc., even when they are apparently aseptic. The cause is probably a slight degree of infection, a sluggish circulation and the dependent position of the part in bed; and the result is pain, followed by swelling of the leg.

The deep lymphatic nodes, three to four in number, lie in front of and internal to the femoral vein, and one of them lies upon the septum crurale (see p. 271). The pathology of elephantiasis, which is more common in the lower extremity than elsewhere, is concerned with the lymphatics of this region which are obstructed by the filaria sanguinis hominis, a small thread worm. This obstruction leads to an enormous increase in size of the extremity from distension of the lymph channels and hypertrophy of the connective tissue.

The crural branch of the genitocrural nerve gives sensory filaments to the skin over Scarpa's triangle, the irritation of which causes the "cremasteric reflex," which consists of the retraction of the testis and is due to the contraction of the cremaster muscle, which is supplied by the genital branch of this nerve. This reflex is most marked in children and young adults and indicates the condition of the second lumbar segment of the cord, which is the spinal center of this nerve.

### The Hip Joint.

**Topography.**—*The center of the acetabulum* lies in Nelaton's line, on or just above the level of the top of the great trochanter and, in the upright position, a little below the level of the upper border of the symphysis. The tuber ischii lies below and behind it. The *center of the head of the femur* lies about two inches directly below the anterior inferior iliac spine, and on a line drawn at right angles to the center of the line connecting the anterior superior iliac spine and the spine of the pubis, about two inches from the latter line. At this point it may sometimes be *felt* in emaciated subjects. The *top of the head of the femur* is  $\frac{3}{4}$  inch above the upper border of the great trochanter. The portion of the *great trochanter* which is most external and subcutaneous is about one inch below its upper margin. According to Hueter the top of the great trochanter is relatively higher in the child owing to the relative shortness of the neck.

The cartilage-covered portion of the *femoral head* is somewhat more than a hemisphere and has a radius of about an inch. The superior and anterior aspects of the head are rather more covered by cartilage than the inferior and posterior. The depression for the ligamentum teres, behind and below the center of the head, is a little below the point reached by the prolongation of the axis of the neck. The articular or cartilage-covered surface of the *acetabulum* is horseshoe-shaped, 1 to  $\frac{1}{2}$  inch in width, and encloses a thin non-articular area of bone. The latter area is seldom fractured, for, in spite of its thinness, it does not receive the direct impact of the femoral head, on account of

the shape of the cavity. According to Tillaux, one of the chief functions of the *ligamentum teres*, as indicated by its oblique direction upward and inward to the head of the femur, is to arrest the pressure of the head against the bottom of the acetabulum. In rare cases suppuration in the hip joint may reach the pelvis, or vice versa, by perforating this thin area. Before the eighteenth year, when the *Y-shaped cartilage* uniting the three bones which meet in the acetabulum has ossified, perforation may occur through the cartilage and the acetabulum may be broken up into its three parts by disease. The bone just above the acetabulum is very thick to transmit the weight of the trunk to the head of the femur (see p. 348). The acetabulum measures 30–35 mm. in depth in the male, less in the female, and it averages 5 cm. in diameter at its rim.

FIG. 104.

Ligaments of the hip joint of the left side. Anterior view. (JOESSEL.)

The strength of the hip joint depends not only upon the shape of the bones but also on the strength of the connecting ligaments and of the surrounding muscles and tendons. The strongest part of the capsule is the iliofemoral band or *Y* ligament, which is a quarter of an inch thick in its thickest part and is one of the strongest ligaments of the body, being capable of sustaining a strain of from 250 to 750 pounds (Bigelow). This ligament is of the utmost importance in dislocations of the hip joint in determining both the position of the limb and the methods of reduction by manipulation and it is almost never torn. The thinnest and weakest parts of the capsule are on either side of the pubofemoral band. The thin part in front of it is just below and external

to the iliopubic eminence, between the pubo- and iliofemoral bands, and *under the bursa* between the iliopsoas and the joint capsule. There is often a defect in this thin area, so that the bursa and the joint are only separated by synovial membrane, and the latter is also sometimes wanting, making a direct communication between the two. This explains how pus in the joint can readily perforate or extend into the bursa and so come to lie beneath the iliopsoas, and also how a psoas abscess may occasionally invade the joint. The *thin area behind* is internal to the pubofemoral band and at the posterior and lower part of the capsule. The *rupture of the capsule* in dislocation of the hip occurs most commonly in this area. When the joint is distended with effusion the swelling naturally first appears at these two thin areas, which are accessible to pressure and correspond to the most marked and earliest tenderness.

The cotoyloid ligament closely embraces the head of the femur external to its greatest diameter and, by preventing the entrance of air, holds the head in place by atmospheric pressure, when the capsule and the surrounding muscles are divided. Hence in excision or amputation of the hip joint this ligament is divided to permit the removal of the head from the socket. Opening an abscess connected with the hip joint does not increase the risk of pathological dislocation, unless the abscess also communicates with the space between the head and the socket and has destroyed the continuity of the cotoyloid ligament or has eroded the head embraced by it. The cotoyloid ligament levels over the slight depressions of the margin of the acetabulum, where the pubis joins the ilium and the latter the ischium. Hence these slight depressions can have no influence upon the mechanism of dislocation as supposed by Malgaigne.

No definite function is agreed upon for the *ligamentum teres*. According to Hyrtl, the vessels which it was supposed to carry to the head of the femur do not reach the latter, but bend around into the efferent veins. Although put on the stretch by adduction and outward rotation these movements are limited by other and stronger ligaments (see p. 437). Surgically it must first be destroyed or cut before the head can be removed from the socket. Unless abnormally long it is always torn in dislocations, except in the congenital variety in which it is lengthened, even to 6 or 8 cm.

Owing to the direction of the neck of the femur the two most important movements of the hip, *flexion and extension*, cause a rotation of the head in the socket without its projecting far from the latter and thus pressing unequally upon the capsule. Hence the hip joint is very secure in these two principal movements. In the other movements the head projects from the socket on the side opposite to that toward which the movement takes place. As one of the factors of *rupture of the capsule* is pressure of a projecting portion of the head against a weak part of the tense capsule, *dislocation is not likely to occur* during simple flexion, although the thin posterior part of the capsule is then tense, but in flexion combined with adduction, abduction or rotation. In

rotation also the head projects from the socket, for the axis of rotation does not coincide with that of the neck.

*The movements of the hip joint are limited as follows:* extension by the iliofemoral band; flexion by contact of the soft parts in the groin, when the knee is bent, and by the hamstring muscles, when the knee is extended; abduction by the pubofemoral band; adduction by the outer part of the iliofemoral band and capsule; rotation outward by the iliofemoral band (its inner part during extension, its outer part during flexion); rotation inward by the ischiofemoral band, during flexion, by the iliofemoral band, during extension.

The *hip joint*, owing to its deep position and thick covering of soft parts, is *not very liable* to attacks of *acute inflammation* from injury, exposure, etc., to which other joints are liable. It seems however particularly *susceptible to chronic inflammation*. Thus it is a favorite site for senile *rheumatoid arthritis* in which the cartilages and bony surfaces are eroded, the latter eburnated and osteophytic processes developed around the joint surfaces, so as to impede its movements.

**"Hip Disease" or Coxitis.**—Still more common and important is the occurrence of tubercular inflammation of the joint known as hip disease or coxitis. In the great majority of cases it commences in early childhood. In this condition *the limb assumes certain characteristic positions* at various stages. In the *first stage* the thigh is *flexed, abducted and slightly everted*. This is the *position of greatest ease* and is that assumed by the limb when fluid is forcibly injected into the joint as in it the joint holds the most fluid. Hence it depends upon the effusion and is *assumed to diminish the tension* and thereby relieve the pain. This is borne out by the fact that, in cases where the primary lesion is within the bone and there is no effusion at first into the joint, this first position of flexion, abduction and eversion, is not observed, but the limb becomes at once adducted and rotated in. According to some this position, as well as that assumed later on, is *due to the reflex contraction of muscles* which are supplied by branches of the same nerves that supply the joint, i. e., anterior crural, obturator and branches of the sacral plexus. The *flexed thigh is made to appear straight by lordosis*, or the extension of the thoracolumbar spine, which tilts backward the pelvis and therewith the femur without any movement in the sensitive diseased joint. The patient can thus stand or lie with both limbs apparently straight. The *lordosis can be detected* by moving the thigh when the patient lies on a table. When the thigh is flexed to the angle at which it is fixed (in flexion) the lordosis disappears, in other words when the lordosis is made to disappear the degree of flexion is shown. If we continue to flex the thigh the spine becomes still more straightened, so as to squeeze the hand placed between it and the table. When the thigh is again extended the lordosis can be felt to return.

To overcome the *abduction* and to restore the parallelism of the limbs, without movement in the diseased and painful joint, *the pelvis is tilted down on the diseased side and up on the sound side*. This would ab-

duct the sound limb which is corrected by its being adducted. Owing to the tilting of the pelvis the *diseased side* is lowered and *appears lengthened*, the sound side appears shortened (Fig. 77). If the tilting of the pelvis be corrected the limb on the side of the disease is found abducted, the sound limb adducted. Hence on measurement from the anterior superior iliac spine (see page 352) we get measured shortening on the diseased side, though at this stage there is no difference in length. The measured shortening is also increased by the flexion. Thus we get apparent lengthening, measured shortening and real equality of the limb on the affected side as compared with the opposite side.

**Second Stage.**—After a variable time *the thigh becomes adducted and rotated inward*, still remaining *flexed*. This is probably due to *reflex muscular contraction*. The adductor muscles are supplied by one of the principal nerves (obturator) that supply the hip joint, but the inversion is perhaps less easily accounted for.

Again in this position *to conceal the adduction* and to restore the parallelism of the limbs *the pelvis is tilted up* on the affected side and the opposite thigh is abducted. Hence there is apparent shortening and measured lengthening (in adduction) on the sound side. The *actual length* of the limb may or may not be affected, but if the disease progresses the limb is shortened by disintegration of the head of the bone, or by its *dislocation* onto the dorsum ilii. This dislocation is favored by the disintegration of the upper and posterior margin of the acetabulum, and the softening of the capsule.

On account of the deep position of the hip joint *pus* formed in the course of hip disease does not soon reach the surface, but, remaining pent up, it is apt to burrow in various directions and become very destructive in its results. The *epiphysis* that forms the head is wholly *within the joint*, and the *conjugal cartilage* that unites it with the diaphysis, and ossifies about the nineteenth year, is usually involved when the primary lesion is in the bone. This may cause a separation of the epiphysis, or it may arrest the growth of the bone at this end and thus lead to a shortening of the limb, unless compensated by increased growth at the lower end.

The well-known fact that patients with hip disease often complain of *pain in the knee*, in excess of or to the exclusion of pain in the hip, is readily explained as a *reflex*. Thus both hip and knee joints are supplied by filaments from the obturator, anterior crural and sciatic nerves, and the irritation of the hip joint filaments is referred to those of the knee.

**Dislocation of the Hip.**—The comparative *rarity* of this injury is due to the great strength of the joint. In spite of the tremendous leverage of the long femur it forms less than 2 per cent. of all dislocations. A considerable proportion (nearly 50 per cent., Prahl) occur before the age of 20. The traumatic dislocations may be practically divided into I. the **backward**, including (a) the *ischiatric* and (b) that onto the dorsum ilii, and II. the **forward or inward**, including (a) the *obturator* and (b) the *pubic*. The *backward dislocations* are by far the most com-

mon. The indispensable *prerequisites for a dislocation* are rupture of the capsule, of the ligamentum teres and, to a less extent, of the cotyloid ligament. Naturally the *thinner parts of the capsule* are those generally torn; the iliofemoral band is almost never torn, a fact of the utmost importance which is due to its strength and the fact that it is relaxed when the luxation is produced. The *position of the limb* in which dislocation most often occurs is that of flexion, adduction and inward rotation. In this position the head of the bone presses upon the thin postero-inferior part of the capsule, which tears and allows the head to be dislocated downward over the lower and weaker portion of the cotyloid rim. The *primary displacement* is therefore downward. The *secondary displacement* is such as may be allowed by the intact portion of the capsule, and especially the iliofemoral band, which is now rendered tense. The attachment of the latter to the femur forms a *new center of motion*, or the fulcrum of a lever of which the head and neck are the short arm and the rest of the femur the long arm. If then the thigh be partly lowered (extended) while the adduction and inward rotation remain unchanged, the head glides up behind the acetabulum to a dorsal or backward position. If, on the other hand, the thigh is abducted or rotated out as it is lowered, the head and neck, moving on the new center of motion, are forced in the opposite direction to the shaft and are displaced inward and forward. This is exemplified in the reduction of dislocations. When there is a backward dislocation the head of the bone is brought below the acetabulum by increasing the flexion, and it may readily be converted into an inward dislocation by too much abduction or outward rotation, especially if upward (forward) traction on the thigh is omitted. In the reduction of obturator dislocations Bigelow gives preference to converting it into the dorsal form by the reverse of the above process.

**In dorsal or backward dislocations** the *head* of the bone lies behind and above the acetabulum, either just behind the latter and in front of the spine of the ischium, (*a*) *ischiatric form*, or higher up on the ilium, (*b*) *dislocation onto the dorsum ilii*, in front of, and seldom above, the apex of the great sciatic notch. In the recumbent position the latter lies directly behind the anterior superior iliac spine. The *head* can be *felt* in the buttocks, above the tuber ischii, beneath the gluteus maximus. The *great trochanter* is displaced forward and approaches nearer the iliac crest than normally. It lies from 2 to 3 cm., above Nelaton's line in the ischiatric form, and from 3 to 7 cm., in the iliac form. The *real shortening* varies within these limits; the *measured shortening* is increased by the flexion present, but may be decreased or even wholly lacking by reason of the adduction; the *apparent shortening* is increased by the adduction and flexion. The head may pass above or below the obturator internus tendon. Although Bigelow classed all cases in which the head was below the tendon as ischiatric and all above as iliac, many if not most of those called iliac pass below the tendon. The flexion and inversion are greater when the

head lies below the obturator tendon. The higher up the head rests, the further up on the posterior aspect is the capsule torn. Usually the quadratus femoris and sometimes the obturator internus and even the pyriformis tendons are torn. The limb is held somewhat flexed, adducted and rotated in. This position can be readily exaggerated but the attempt to give it the opposite position is resisted. The tension of the iliofemoral band and of the iliopsoas muscle and the position of the head and neck, which must follow the plane on which they lie, are largely responsible for the position assumed and the resistance to movement in the opposite direction. The normal depression behind the trochanter is lost and the depressibility of the soft parts below the outer half of Poupart's ligament, where the head lies normally, is increased.

In the inward or forward dislocations the head of the bone passes forward from below the acetabulum, along its inner edge, until it reaches the thyroid foramen, (a) **thyroid form**, or, if the limb is further extended and everted, it may pass forward and come to lie upon or near the iliopubic eminence, (b) **pubic form**. In both forms the head can be distinguished by touch or even by sight in its new position, especially in the pubic variety. In the latter variety the *femoral artery* can be felt pulsating directly over it, or to its inner side. The *great trochanter* is displaced inward toward the acetabulum, over which it may be felt. The outer and posterior portions of the hip are flattened. Both the obturator and anterior crural nerves have suffered from pressure. The posture of the limb varies. In the **thyroid variety** it is flexed, abducted and usually rotated out. There is *apparent lengthening* by reason of the tilting of the pelvis, to bring the abducted limb into line. The measurement may show lengthening on account of the downward position of the head, in spite of the shortening due to abduction. In some cases the head has passed over the ramus into the perineum. In the **pubic variety** the limb is but little if at all abducted, markedly everted and but little flexed. In this form the apparent lengthening of the thyroid form may be wanting, if there is no abduction, and there is measured and actual *shortening*. From its position (eversion) and the presence of shortening it may be mistaken for fracture of the neck of the femur, but it can be distinguished from it by the presence of the head in its new position, the depression and inward displacement of the trochanter, and the flattening of the outer aspect of the hip.

In the reduction of dislocations of the hip we may lay down the *general rule* that the head should be made to take, in the reverse direction, the route it took in becoming dislocated. The *chief obstacle* to reduction is the tension of the Y ligament in the partly extended position, and to overcome this the thigh is first flexed. This flexion also brings the head down to the lower part of the socket, where it escaped. As a general rule we may direct to first (1) *increase the deformity and then (2) make the opposite movements.* (1) Relaxes the Y ligament, releases the head and brings it below the socket while (2) forces the

head through the tear in the capsule into the socket. *In the dorsal form* increasing at first the adduction and inversion lifts the head of the femur away from the pelvis and the projecting rim of the acetabulum. At the same time unless we make forward traction after flexion, and otherwise increasing the deformity, a backward dislocation is likely to be converted into a forward one and vice versa. In other words the *reduction* is to be made *largely by traction* rather than by manipulation. The spasmodic contraction of the muscles opposes this forward traction, hence the value of anaesthesia. *Stimson's method* of placing the patient on the face with the flexed thigh hanging over the end of the table, enables us to dispense with anaesthesia; for the weight of the limb, tiring out and overcoming the contraction of the muscles, serves instead of traction, so that a slight rocking of the flexed limb accomplishes the reduction. The *forward or inward forms* may be *reduced* by first converting them into the backward form by increasing the deformity and then making the opposite movements without traction, or they may be reduced directly by the same manipulations with traction, taking care not to carry the opposite movements too far. It may be convenient to remember that the *internal condyle* looks nearly in the same direction as the head of the femur.

**Congenital Dislocations of the Hip.**—The hip may be congenitally dislocated from lack of development of the acetabulum, especially its upper or iliac portion. In congenital dislocations the neck is short and the head is flat and slips onto the dorsum of the ilium when the child walks. If reduced there is nothing to keep it from slipping out again. When long displaced the muscles become shortened so that the head can not be reduced without dividing them. A new socket may form on the ilium from osteophytic outgrowths. The ligamentum teres is usually stretched and not torn.

**Fractures of the Neck of the Femur.**—The *long axis* of the neck measures  $3\frac{1}{2}$  to 4 cm., its vertical diameter averages 36 mm., its antero-posterior 25 mm. The neck forms *an angle* with the shaft, averaging  $125^{\circ}$  in the adult. This angle is greater in the infant, but does not decrease after adult life is reached. Hence the theory that the frequency of fractures of the neck of the femur in old age depends upon a decrease of this angle to one nearer a right angle, a position that would favor fracture, is not sustained by facts and has been abandoned. Nor is the angle sufficiently less or the trochanter enough more prominent in the female to account for the more frequent occurrence of this injury in that sex.

The fact remains, however, that this fracture is *essentially a lesion of old age*, is more common in women than in men and is *often the result of slight causes*, a stumble, a misstep, or a slight fall. These facts indicate the existence of *senile changes as a predisposing cause*, and it is found that all parts of the bone are much rarefied and the cortical substance is much thinner in the aged. This *osteoporosis* affects also two plates of compact bone which strengthen the neck, (1) the *calcar femorale*, a nearly vertical plate projecting into the spongy substance,

toward the great trochanter, from a little in front of the small trochanter, and (2) *a thin dense plate*, continuous with the posterior surface of the neck, which extends in the spongy tissue toward the outer surface of the shaft and of the trochanter. As the *capsule is attached* in front to the base of the neck (the intertrochanteric line) and behind half an inch or more internal to the posterior intertrochanteric line, it follows that there can be *no strictly extracapsular fractures* of the neck, for the latter is entirely intracapsular in front. A more scientific classification of these fractures than that into intracapsular and extracapsular is the division into (a) fractures through the neck and (b) fractures at the base of the neck.

(a) **Fractures through the neck** may occur at any point between the junction of the head and neck and the base of the latter, though they are said to be *more common near the head*. It is this variety especially that occurs from slight violence in the aged. As a rule there is *angular displacement* at the fracture, from the crushing of the bone or the penetration of one fragment into the other posteriorly, so that the neck is bent at an angle directed upward and forward. If the fracture is near the head the latter is penetrated by the smaller and more compact neck, but true impaction is rare. The *periosteum* is usually *untorn* over a portion of the circumference of the neck. This periosteum is reinforced by fibers reflected from the femoral attachment of the capsule toward the head in three bands or retinacula, one behind and one at either end of the anterior intertrochanteric line. The *untorn portion* of the periosteum not only holds the fragments together, but *furnishes a source of blood supply* to the smaller fragment, to assist in the process of repair. The only other source of blood supply of the head, after fracture, is the ligamentum teres.

(b) **Fractures at the base of the neck** usually *follow* the line of junction of the neck and shaft quite closely, but other lines of fracture traverse the great trochanter, as a rule. *The neck is as a rule bent backward* by the crushing of its posterior and more fragile part, or its penetration into the trochanter posteriorly. In this way the trochanter may be split into two or many pieces. According to Stimson true impaction, or fixation with penetration, is the exception. In this form *the cause* is usually a fall on the trochanter, and it includes most of those cases where fracture occurs before old age. According to Whitman it is more common in childhood than was formerly supposed. *The axis of the neck and of the great trochanter* are not in the same plane, but meet in an angle, open posteriorly, at the anterior trochanteric line. In a fall on the trochanter this angle is exaggerated and the bone gives way here at the weakest and most spongy portion of the bone. This mechanism helps to explain the greater penetration behind and the eversion of the limb.

The *essential point in the prognosis*, and the reason for attempting to distinguish between these two forms, lies in the vitality and *power of repair of the upper fragment*. This depends not so much upon impac-

tion or the situation of the fracture as upon the preservation of the blood supply, which runs toward the head in the thick cervical periosteum. These vessels are not much injured in fractures at the base of the neck, and in those through its narrow part we have seen that enough of the periosteum is usually untorn to preserve the vitality of the fragment. The number of specimens of undoubted bony union after fracture of the narrow part of the neck is sufficiently large not only to demonstrate its possibility, but to indicate that it is probably common enough, with proper treatment, to justify the attempt to obtain it.

**The symptoms and signs** of fracture of the neck of the femur, *upon which the diagnosis depends*, are (1) interference with function, (2) localized pain on movement, (3) position of the limb, (4) crepitus, in a few cases, (5) enlargement or widening of the great trochanter from comminution, especially in fractures at the base of the neck, (6) elevation of the trochanter and its approach to the median line, (7) swelling and diminished depressibility of the region below the outer half of Poupart's ligament. In addition to these the cause of the injury is important, especially if it be trifling and in an aged person. As to the posture the injured limb is everted, slightly flexed, abducted and it may appear shortened. The cause of eversion is largely the effect of gravity in connection with the diminished activity of the muscles; it also depends upon the angular displacement, with or without impaction. In addition the upward displacement relaxes the internal rotator muscles more than the external, so that the former can act only at great disadvantage. Inversion is sometimes present instead. Shortening is due (1) to overriding and (2) to alteration of the angle of the neck; it varies from 2 to 6 cm. It is usually greater in fractures at the base of the neck. In those through the narrow part of the neck it may be slight or even wanting at first, and increases gradually, or sometimes suddenly, after a few hours or days. A slight primary shortening and its subsequent gradual increase is thought by many to be pathognomonic of fractures through the neck. Allis called attention to the relaxation of the fascia lata between the crest of the ilium and the great trochanter as a result of the elevation of the trochanter. Rotation of the trochanter upon a shorter radius than normal is a theoretical rather than a practical sign.

An exact diagnosis in all cases between "intracapsular" and "extra-capsular" fractures is both impossible and useless. Some cases of fracture at the base of the neck (extracapsular) can be positively recognized by the splitting and broadening of the trochanter and the immediate and considerable shortening. Likewise slight violence, advanced age, great disability and slight shortening point to fracture through the narrow part of the neck.

In general the treatment should aim to secure union, by means of fixation and traction. The full restoration of form and function is not often to be expected. Fairly good function is not uncommonly present after such injuries.

**Separation of the epiphysis**, whose conjugal cartilage adjoins the head, has been demonstrated by specimens in a few cases, but it is even rarer than fracture of the neck at the corresponding age, *i. e.*, before nineteen, when bony union occurs (see p. 438).

The **great trochanter** is formed as a *separate epiphysis*, which in a few cases has been observed to be separated from the shaft, sometimes as the result of osteomyelitis. Bony union occurs in the eighteenth year.

**Coxa vara** is an affection of adolescence, usually rachitic in origin. Under the weight of the body the neck yields, its angle with the shaft is reduced to  $90^{\circ}$  or less, the limb is shortened and the trochanter is elevated and made more prominent. Hence it may be mistaken for hip disease or congenital dislocation of the hip.

**Excision of the head of the femur** is sometimes called for in hip disease. The chief anatomical interest in the operation concerns the *method of reaching the deeply placed joint*. An **external incision** (Langenbeck's operation) has been much employed. With the thigh flexed at an angle of  $45^{\circ}$  and rotated a little inward an incision of 4 to  $4\frac{1}{2}$  inches is made in the long axis of the limb, so that one third of the incision is over the great trochanter, a little behind its center, the remaining two thirds over the ilium, reaching up to the top of the great sciatic notch. In the position in which the limb is placed it would meet the posterior superior spine, if prolonged. The gluteal muscles are divided in a direction parallel with their fibers, and the capsule is opened in the same line, and also transversely near the acetabulum. *By cutting the cotyloid ligament air is admitted* behind the head, thereby equalizing the atmospheric pressure on its two sides so that it is readily separated from the acetabulum. This same procedure is carried out in exarticulation at the hip joint, but in the latter operation the ligamentum teres requires division, while in excisions it has usually disappeared as a result of the lesion for which the operation is required. Among the disadvantages of the external incision is the fact that many large and important muscles and many of the arteries that meet about the great trochanter are divided. Two methods of anterior incision may be mentioned. In one (Lücke's) the incision is made in the long axis of the limb from a point half an inch below and internal to the anterior superior iliac spine, just external to the anterior crural nerve, exposing the inner border of the sartorius. The rectus and sartorius are retracted externally, the psoas internally, exposing the capsule in front. But it is difficult to draw the psoas aside, the capsule must be opened through the iliofemoral ligament, and the external circumflex artery can hardly escape division. Hence the incision of Hueter, Parker or Barker is preferable. This is carried downward from half an inch below the anterior superior iliac spine; the tensor vaginae femoris and the glutei muscles are retracted outward and the sartorius and rectus inward, exposing the capsule more externally. No muscles and no vessels or nerves of any importance are divided.

**Amputation or exarticulation of the thigh at the hip joint** is performed by various methods. The control of hemorrhage is the essen-

tial feature of the operation and may be *accomplished in several ways*. (1) The femoral artery may be ligated before the flaps are cut or while they are being formed as in the "anterior racket" incision. (2) The femoral may be compressed in the flap by the fingers of an assistant, just before the vessels are cut. The fingers are introduced behind the vessels, which are compressed between them and the thumb which is on the surface. These methods do not control the bleeding from the branches of the internal iliac. Hence (3) pressure on the lower end of the aorta by Lister's tourniquet has been used and also (4) pressure on the common iliac against the pelvic brim by Davy's lever introduced into the rectum. Both 3 and 4 have been generally abandoned. (5) Pressure on the common iliac by the fingers of an assistant introduced through an intermuscular incision in the iliac region (McBurney), I have found very serviceable. (6) The elastic tourniquet around the upper end of the limb, with or without the use of long needles, or skewers, thrust through the upper end of the thigh, to prevent the rubber tubing or bandage from slipping down, is the *method most generally used*. In order to control the gluteal and sciatic vessels the tourniquet must be carried internal to the tuber ischii, so as to compress them as they emerge from the great sacro-sciatic foramen. By passing over the groin it compresses the femoral vessels and by being carried above the iliac crest it is prevented from slipping downward.

The *varieties of incision* are numerous. We may make an "external racket" or oval incision, with the summit two inches above the trochanter; an "anterior racket" incision, with the center at the middle of Poupart's ligament; or a circular amputation of the thigh combined with an external vertical incision extending up two inches above the trochanter, etc. The various incisions have their own advantages and disadvantages. *The vessels divided* are the femoral, profunda, gluteal, sciatic and branches of the external and internal circumflex, and the long saphenous vein. Their position at the point of section varies with the form and length of the flaps. In those methods with long flaps the branches of the gluteal and sciatic arteries are small and unimportant. In the "anterior racket" incision no tourniquet or compression is used, the vessels are tied as they are met with, as in removing a tumor, and very little blood need be lost. *The muscles attached to the great trochanter and the upper end of the shaft are divided close to the bone*; the other muscles, sartorius, rectus, adductors, gracilis and hamstring muscles, are divided at varying levels.

## THE THIGH.

**Limits.**—Under this term is included the region lying below the regions last described, *i. e.*, below the level of the gluteal fold, and above the subcrural bursa of the knee, *i. e.*, 5 to 8 cm. above the patella. It is more or less conical in *shape*, and slightly convex in front and externally. *On cross section* it is round in the female, by reason of the subcutaneous fat, triangular in the male, with its base behind. The thigh is directed obliquely downward and inward, the

inward obliquity being more marked in the female, on account of the wider separation of the acetabula, and also in short subjects.

**Surface Markings and Landmarks.**—The *rectus muscle* forms a prominence in front, most noticeable when the muscle is in action. On either side of this prominence, and most conspicuous in the lower half of the thigh, is a *slight eminence* formed by the *vasti muscles*, the inner one being the more marked. Along the inner aspect of the thigh, from the apex of Scarpa's triangle, is a *groove* indicating the interval between the *adductors* and the *quadriceps femoris*. In this groove lie the *femoral vessels* and, more superficially, the *sartorius muscle*. The outer surface of the thigh is flattened or slightly depressed by the *iliotibial band* of the *fascia lata*. At the junction of the external and posterior aspects of the thigh the position of the *external intermuscular septum*, corresponding to the interval between the *hamstring muscles* and the *vastus externus*, is indicated by a slight depression, and is perceptible to palpation. The bone can not be plainly palpated.

**Topography.**—The line of the *femoral vessels* (see p. 431) and the *sciatic nerve* (see p. 427) have already been given. The *sciatic nerve* usually *bifurcates* near the middle of the thigh and its *internal popliteal branch* continues the direction of the trunk. The *long saphenous vein* follows the course of the inner border of the *sartorius muscle* in a line from the *saphenous opening* (see p. 431) to the posterior border of the muscle at the level of the *internal condyle*. It is not infrequently double in the thigh. The *long saphenous nerve* follows the *femoral artery*, crossing to its inner side in front of the artery in Hunter's canal. Emerging through the anterior wall of this canal it passes under cover of the *sartorius* in the lower fourth of the thigh and lies to the inner side of the knee.

The **skin** of the thigh is coarse on the outer side, thin and fine internally, and is often used in *skin grafting*. Its *loose attachment* to the deep *fascia* favors the performance of *circular amputations*, as no dissection of a skin flap is required, merely the upward retraction by an assistant. Along the line of the *external intermuscular septum* it is a little more adherent and may require freeing with the knife. The *laxity of the subcutaneous tissue*, which contains a very variable quantity of fat, allows the stripping up of large flaps of skin or the formation of extensive extravasations beneath it, in case of injury. According to Tillaux, the *long saphenous vein* is contained in a sheath derived from the *fascia lata* in the middle third of the thigh, elsewhere it is subcutaneous.

The **fascia lata** resists the extension of tumors, abscesses and deep extravasations of blood, especially on the outer aspect where it is stronger. Through rents or cuts in the *fascia lata* the underlying muscle has occasionally bulged and been caught forming a so called *hernia of the muscle*. The *quadriceps* and *adductor longus* have been thus herniated. From the deep surface of the *fascia* two fibrous septa pass inward to the two lips of the *linea aspera* and divide the thigh into an anterior and a posterior compartment. This division has little surgical

## PLATE LII.

FIG. 105.

Cross section of the middle of the right thigh.

Upper segment of the section. (Tillaux.)

importance. The *internal intermuscular septum* separates the vastus internus from the adductors, and is very thin and unimportant. The *external* separates the vastus externus from the hamstring muscles. According to Tillaux another septum, passing outward from the fascia lata at the junction of the inner and posterior aspects to the external intermuscular septum, separates the adductor from the hamstring group of muscles.

The femoral artery may be ligated at any part of its course, which has already been given (see p. 431). The "place of election" is at the apex of Scarpa's triangle. It may also be ligated at the base of the triangle (common femoral) or in Hunter's canal. The latter lies at the lower end of the middle third of the thigh, beneath the sartorius muscle, which is retracted internally to reach it. It measures five to six cm. in length, and is bounded by the adductor longus behind, the vastus internus externally, and in front by a firm membranous layer of oblique tendinous fibers passing from the adductor magnus downward and outward to the vastus internus. The vein here lies behind and somewhat external to the artery, quite closely connected with it, and an extra vena comes may lie in front of the artery and complicate its ligation. The long saphenous nerve lies in the canal, in front and slightly external to the sheath of the vessels. Within the canal it crosses in front of the vessels, which it accompanies to the opening in the adductor magnus, where it perforates the canal and passes beneath the sartorius. The vastus internus separates the artery from the femur on the outer side of the vessel, so that in compression of the artery, which must be made from within outward, there is no firm bed against which to compress it. In rare instances the femoral artery is replaced by two trunks. It is occasionally ligated for popliteal aneurism or for wounds.

The great sciatic nerve usually divides into the internal and external popliteal nerves about the middle of the thigh, not infrequently higher up, even within the pelvis, and occasionally lower down. Below the lower border of the gluteus maximus it is quite superficial and a little lower is crossed by the biceps. At the middle of the thigh it lies between the biceps behind and the adductor magnus in front, beneath or anterior to the thin fascial layer separating the hamstring and adductor muscles. Lower down it lies between the hamstring muscles which are internal and external to it. It is surrounded by a layer of loose connective tissue and fat, continued downward from the pelvis. This tissue affords a favorable pathway for the sinking of abscesses, even from the pelvis to the lower thigh or the popliteal space.

The place of election for opening deep abscesses of the thigh or the removal of sequestra from the femur is the external surface, for here the bone is not very deep and there are no important vessels or nerves.

**Fractures of the Femur.**—The shaft of the femur may be fractured at any part, but most commonly at the middle third, which is affected by the leverage of both ends. The fracture is usually oblique,

but may be transverse, especially in children and in direct fractures, which are most common in the lower half. Fractures in the upper half are almost always oblique. The obliquity usually corresponds to the normal curvature of the bone. Thus it commonly runs from behind forward and downward in the middle third, forward and outward in the upper third. The displacement is marked and is the result of the fracturing violence, the contraction of the thigh muscles and the swelling beneath the firm fascia lata, by means of which the thigh is necessarily shortened at the same time that it is swollen. In addition there is an angular displacement, usually directed forward, or forward and outward, in the direction of the natural curve and attributed to the contraction of the adductor muscles, which form the arc of the curve. The lower fragment may also be rotated out by gravity. In fractures of the upper third the usual forward and outward displacement of the lower end of the upper fragment is largely due to muscular action. (1) The adductors and hamstring muscles draw the lower fragment up and in, behind the upper fragment, and tilt the latter forward and outward. (2) The psoas and gluteal muscles also tilt the upper fragment forward and outward. The sharp ends of an oblique fracture may be driven into and caught in the surrounding muscles, which, being interposed between the fragments, prevent reduction of the deformity and lead to delayed union or non-union. The artery or vein are rarely torn or compressed by the fragments, an injury leading to gangrene. I have seen one such case. In fractures in the lower third the lower fragment may be tilted backward, probably by the action of the gastrocnemii.

Except in rare cases of transverse or incomplete fractures, the limb is always shortened. This shortening may vary from a fraction of an inch to four or even six inches, and is due to the overriding and the angular displacement of the fragments. A principal object of treatment is the overcoming of this shortening by continued extension. Practically union never occurs without shortening, though the possibility of union without shortening may be admitted. The average amount of shortening after union is  $\frac{3}{4}$  inch, though  $1\frac{1}{2}$  inches of shortening may occur without a limp in the gait, the shortening being compensated by the tilting of the pelvis. In this connection it may be noted that the lower limbs are usually of unequal length, the inequality averaging  $\frac{1}{4}$  inch, the left being the longer as a rule (Wight). In only about 10 per cent. of cases are they of equal length, so that using one limb as a standard of length for the other is inaccurate. In the treatment of fractures of the upper third the entire limb should be flexed and abducted to coincide with the forward and outward tilting of the upper fragment.

In amputation at or below the middle of the thigh the circular method is easy and gives good results. The ease of retraction of the skin flap has been referred to, and the thigh is seldom so conical as to require the splitting of this flap. The muscles retract unevenly, those attached to the femur retracting but little, those not so attached, the

free muscles (sartorius, rectus, gracilis and hamstring), retracting considerably. Hence the stump is retracted and the muscles are divided a second or even a third time.

### THE REGION OF THE KNEE.

**Limits.**—This includes the region between the level of the upper end of the subcervical bursa, 3–4 fingers' breadth or 5–8 cm. above the patella, and the level of the tubercle of the tibia.

#### Landmarks and Surface Markings.—(1) Antero-lateral Region.

—The patella is plainly seen and felt in front, its inner border being somewhat the more prominent. In the extended position of the limb the patella can be moved to and fro, when the quadriceps is relaxed, but is drawn up and firmly fixed against the femur when the muscle is contracted. When the knee is flexed the patella occupies the hollow between the two bones, and is not so readily palpated. In this position we can feel, above the patella and through the quadriceps expansion, the *trochlear surface of the femur*, especially its prominent outer border. A line from the upper angle of this border to the adductor tubercle marks the *level of the epiphyseal line*. The *adductor tubercle* is felt at the upper end of the internal condyle. It is just above the epiphyseal line and is the favorite situation for exostoses in adolescence. The *internal condyle* and its tuberosity are more prominent than the outer, but the *outer tuberosity of the tibia* is more prominent than the inner. The *tubercle of the tibia* is plainly felt at the upper end of the anterior tibial border, and at the lower end of the ligamentum patellæ. About on a level with the tubercle, *the head of the fibula* is felt on the postero-external aspect, 1 cm. below the joint line.

In the semiflexed position of the knee, when the quadriceps muscle is contracted, ~~X~~ the *ligamentum patellæ* can be plainly felt, and often seen, as a ridge extending from the apex or lower end of the patella to the tubercle of the tibia. In this position there is a *slight groove* on either side of the tendon but in the extended position, when the quadriceps is relaxed, the grooves are not marked. In stout subjects the grooves may be obliterated by fat, which is found most abundantly behind the upper half of the tendon, separating it from the synovial cavity. The *ligamentum patellæ* lies in the axis of the leg and hence forms a slight angle with the direction of the quadriceps. *On either side of the patella is a slight groove*, which is obliterated by effusion into the joint and may be filled with fat in the obese. In stout subjects the patella may appear to lie in the bottom of a groove instead of on a ridge. *Above the patella is a depression* which is converted into a prominence in case of effusion into the joint. On both sides, but particularly on the inner side, *the interarticular line* between the tibia and femur can be felt as a slight depression in normal conditions. This is just above the level of the apex of the patella, which serves as a convenient landmark to it. It is here that one feels for a displaced semilunar cartilage. *The iliobial band* of the fascia lata, descending between the patella and the back of the external condyle to

the external tuberosity of the tibia, may be felt as a rounded band, most distinctly when the joint is forcibly extended.

**Posterior or Popliteal Region.**—In this region the landmarks are best felt when the knee is slightly flexed. In this position the concavity of the space appears, while in the extended position it is flat or bulging. At the outer side, behind the iliobial band, the *tendon of the biceps* is felt descending to the head of the fibula. Directly in front of it the upper part of the *external lateral ligament* is palpable, and close to its inner border the *external popliteal nerve* is readily felt as a rounded cord. In its descent the nerve crosses the neck of the fibula, where it may be rolled under the finger before it enters the peroneus longus. The *internal popliteal nerve* may be felt and, in thin subjects, even seen descending vertically in the middle of the space. On the inner side from without inward we can feel the long and slender tendon of the *semitendinosus*, the thicker and less prominent tendon of the *semimembranosus*, and the *gracilis*. The last two appear as one tendon but by a little manipulation we can insinuate the finger between them. The *popliteal lymph nodes* when normal can not be felt. At the lower end of the space we can feel the converging fleshy heads of the *gastrocnemius*. In the flexed position a *crease in the skin* crosses this space some distance above the joint line. It disappears in extension.

**Topography.**—The *popliteal artery* enters the popliteal space beneath the *semimembranosus*, a little to the inner side of the middle line, and thence *runs in a line* to the interval between the two heads of the *gastrocnemius* at the center of the lower end of the space. It descends at first obliquely outward, reaches the middle line opposite the joint, and thence runs vertically. It *bifurcates* on a level with the tubercle of the tibia. It lies against the back of the *femur*, the posterior ligament of the knee and the *popliteus* muscle and can be *compressed* against the *femur* in the upper part of the space, where also *its pulsations* can be felt. The *popliteal vein* lies behind it, to its outer side above, but it crosses to its inner side below. The *internal popliteal nerve* descends in the middle line, continuing the course of the great sciatic, and is superficial to the vein, by which it is separated from the artery.

The superior *articular arteries* run transversely just above the condyles of the *femur*; the inferior articular arteries are just above the head of the *fibula* externally, and a little below the internal tuberosity of the *tibia* internally. The deep branch of the *anastomotica magna* descends in front of the *adductor magnus* to the internal condyle, the superficial part runs with the *internal saphenous nerve*. The *short saphenous vein* perforates the deep fascia at the lower part of the popliteal space in the middle line. It is not visible as a rule unless varicose and it has been suggested (Hérapat) that *varices* of this vein *may depend upon a narrowness of the opening in the fascia*. The *long saphenous vein* passes along the back of the internal condyle, above which it lies along the posterior border of the *sartorius*. It is joined by the *internal saphenous nerve* just below the joint line.

**Soft Parts in Front of the Knee.**—The skin is thick and very movable, thus permitting incisions into the joint to be very indirect or valvular when desired. The deep fascia, continuous with the fascia lata, is attached to the two tuberosities and the tubercle of the tibia and strengthens the joint on either side of the patella. This part of the joint is also strengthened by the lateral expansions of the quadriceps tendon, which are connected with the sides of the patella and ligamentum patellæ anteriorly and reach as far as the lateral ligaments posteriorly. Hence they are called lateral patellar ligaments. In fractures of the patella, where there is any considerable separation of the fragments, there is always more or less of a tear in the lateral expansion on either side of the line of fracture.

There are two bursæ in this region that require mention. (1) The prepatellar bursa lies in front of the lower two thirds of the patella and the upper end of the ligamentum patellæ. It does not reach the internal border but often projects over the external border of the patella. Although it is often described as separating the patella from the skin, it lies, according to Tillaux, beneath the deep fascia. Others (Gruber, Joessel, etc.) describe bursæ in three situations; beneath (1) the skin, (2) the superficial fascia and (3) the deep fascia, of which the last is the most constant. When more than one is enlarged they are separated wholly or partly by septa which easily yield to inflammatory changes, so that in opening a purulent prepatellar bursitis a single cavity is often found. The bursa is often enlarged and not infrequently inflamed in those who kneel much, such as housemaids, etc., hence prepatellar bursitis is commonly known as "house-maids' knee." Suppurative bursitis may lead to caries of the patella, from which the bursa is separated only by the periosteum. I have also met with tubercular inflammation of this bursa. (2) The small bursa between the patellar ligament and the tubercle of the tibia is separated from the synovial cavity by a pad of fat lying behind the upper end of the ligament. It does not communicate with the joint and is not often enlarged or inflamed. An indistinct feeling of fluctuation on either side of the upper end of the patellar ligament is often due to the loose fat beneath it and not to an enlargement of this bursa. This fat often protrudes a little on either side of it, and thus still further simulates an enlarged bursa.

The soft parts at the back of the knee either bound or are contained in the popliteal space. The skin covering it is not so movable as in front, and the contraction of a cicatrix resulting from burns, ulcerations or injury may result in a bent knee. In straightening a knee, long ankylosed in the flexed position, the skin at the back is liable to be torn. The deep fascia, continuous with the fascia lata above, has no bony attachments here. Its firmness limits the extension toward the surface of popliteal tumors or abscesses. Hence being pent up in the popliteal space they cause severe pain and tend to spread down into the leg or up into the thigh. From the latter region abscess may extend to the popliteal space through the opening in the

adductor magnus for the femoral vessels, or they may follow the great sciatic nerve from the thigh, the buttocks or the pelvis.

The muscles which *bound the space*, and give it a lozenge shape, are the biceps above and externally, the semitendinosus and semimembranosus above and internally, and the two heads of the gastrocnemius below and on either side. The upper muscles, known as the *hamstring muscles*, are the cause of flexion of the knee in knee joint disease, from the irritation of articular filaments of the sciatic nerve, motor branches of which supply these muscles. Continued flexion in this disease leads to a *partial backward luxation of the tibia* and to the *contracture and shortening of these muscles*. According to Tillaux, the biceps and semitendinosus are frequently shortened in these conditions, the semimembranosus rarely so. The shortened tendons require tenotomy prior to straightening the knee. In *tenotomy of the biceps* the relation of the external popliteal nerve just internal to it is to be borne in mind. Contraction or contracture of the muscle renders the tendon more superficial and increases its distance from the nerve. To diminish the risk of cutting the nerve the tendon should be cut from within outward about 3 cm. above the head of the fibula. The *hamstring tendons*, especially the biceps, may be *ruptured* by violence in the position of extreme flexion of the hip while the knee remains extended, a position in which they are greatly stretched.

The *popliteal vessels* lie deeply and are well protected, hence they are seldom wounded. The artery however is more often the seat of aneurism than any other, with the exception of the thoracic aorta. Many factors have been adduced to account for this disposition. (1) It divides into two large vessels. (2) It is supported by the lax tissue of the popliteal space, and not by muscles. (3) Its course is curved, in the flexed position, like the thoracic aorta. (4) It is subjected to frequent and extensive movement. In straightening the bent knee in cases of chronic knee joint disease the artery may be ruptured. In this respect cuneiform resection of the knee is a safer operation than forcible straightening. *Forced flexion of the knee affects the lumen of the artery* as shown by the diminished pulse at the dorsalis pedis artery. When the artery is the seat of an aneurism, the pressure exerted by forced flexion of the knee stops the circulation, and popliteal aneurisms have been successfully treated in this way. The *relations of the artery to the vein and the internal popliteal nerve* explain the oedema of the leg and the nerve symptoms due to the pressure of an aneurism on these structures. The close relations of the artery to the posterior ligament, on which it lies, explains the occasional penetration of an aneurism into the joint. The artery is more closely connected with the posterior ligament below than above the joint line, hence Tillaux recommends sawing the tibia from behind forward in resection of the knee to avoid accidental wound of the artery, but this is not necessary with ordinary care. A backward luxation of the tibia has occasionally been complicated by rupture of the artery. *Anomalies of the artery* are rare and consist mainly in a high division.

PLATE LIII.

FIG. 106.

Popliteal region of the right side. (Joessel.)

The popliteal vein is so closely adherent to the artery that some difficulty may be found in separating the two in ligature of the latter. In spite of its more superficial position than the artery, the vein is ruptured by violence even less often than the artery and, according to Treves, never alone. This may be owing to the circumstance, noted by Tillaux, that it is so thick that it does not collapse on section, and thus resembles an artery so closely that it may readily be mistaken for it in operations on the cadaver.

The lymph nodes of the popliteal space consist of only four small nodes, one just beneath the fascia and below the opening for the short saphenous vein, the others along the artery. They are rarely swollen and, when involved, form a median tumor, unlike those derived from the bursæ.

The bursæ at the back of the knee are situated *on either side*, two on the inner and four on the outer side. Many of these are not constant and are unimportant on account of the fact that they never communicate with the joint and are seldom enlarged.

1. Between the internal condyle and the inner head of the gastrocnemius and extending between the latter and the semimembranosus is the *largest bursa* of this region and the *one most often inflamed*. It *communicates with the joint* in fully fifty per cent. of cases (Gruber) and more often in adults and in robust subjects. Its slit-like opening into the joint may become closed by the tightening of the posterior ligament in extension, which may explain its firm feeling in extension, in contrast with its more flabby feeling in flexion. In the latter position it may sometimes entirely disappear on pressure. It may become enlarged in effusions into the joint, or independently. (2) A small inconstant bursa, between the semimembranosus and the tuberosity of the tibia, may communicate with (1) but never directly with the joint. On the outer side there is (3) a bursa between the popliteus tendon and the external lateral ligament, without joint connection, and (4) one between the same tendon and the external tibial tuberosity. The latter bursa is strictly a *diverticulum from the joint* and, by occasionally communicating with the upper tibiofibular joint (in about fourteen per cent. of cases, Gruber), connects the latter with the knee joint. (5) A bursa between the outer head of the gastrocnemius and the external condyle is neither constant nor connected with the joint. (6) One between the biceps and the external lateral ligament is more constant but is also not connected with the joint. Tumors due to a *bursitis* are situated laterally and usually internally, but median cysts may occur in the popliteal space due to the hernial protrusion of the synovial membrane through small openings in the posterior ligament.

The knee joint owes its strength to that of the ligaments, tendons and fasciæ, which join together and surround its component parts. By reason of its strength and the large extent of its opposing surfaces, traumatic dislocation is *uncommon* in spite of its exposure to injury, and only occurs from severe violence. The most common form is dislocation of the tibia forward by direct violence or by hyperextension,

the next commonest is dislocation of the tibia backward. The *lesion is a grave one* because of the great violence required and the frequency of compounding and of injury of the popliteal vessels.

When the femur is held vertically the plane of the lower surfaces of the two condyles is not horizontal, as is that of the upper surfaces of the tibia, but the *inner condyle* projects *lower than the outer*. Hence to make the joint surfaces parallel the *femur must be inclined inward*, the position it normally occupies in the body. Another result of this inclination is to bring the knees together, although the hips are widely separated, and, as the tibia descends nearly vertically, the ankles are also in contact.

In the condition known as **knock knee** or *genu valgum* the knee is unusually prominent internally. This condition is *due to* an overgrowth of the internal condyle, unevenness of the tibial facets, curvature of the bones, or relaxation of the internal ligaments of the joint, with or without contraction of the tissues on the outer aspect. *Overgrowth of the internal condyle is the common cause*, and may occur primarily or as the result of relaxation of the ligaments on the inner side. By this relaxation the pressure between the bones on the inner side is diminished, but the actual separation of the bony surfaces, thus rendered possible, is prevented by the downward growth of the inner condyle. The pressure between the bones on the outer side is increased, whereby the latter undergo some atrophy and the deformity is thus increased. Knock knee is *commonly due to rickets* and occurs most often between the ages of two and four. When it occurs in adolescents it is not commonly due to rickets but to a relaxation of the ligaments and muscles. According to Mikulicz, the increased downward growth of the inner condyle is confined to the lower end of the diaphysis. The prominence of the internal condyle is readily recognized when the knee is sharply flexed. It is a curious fact that *the deformity, however great, disappears completely when the knees are flexed*. This is because the deformity is due to the greater length of the internal condyle so that the axis of the hinge motion is not transverse but inclined outward and upward, bringing the feet away from one another when the knees are extended but together when they are flexed. Knock knee, when well established, is *treated by osteotomy of the femur* above the condyles, with or without the removal of a wedge of bone (*cuneiform osteotomy*), and then by straightening the limb.

**Ligaments.**—In the semiflexed position of the joint most of the ligaments are relaxed, a condition that favors the backward displacement of the tibia by the contracture of the hamstring muscles, in chronic knee joint disease with flexion. Owing to the relaxation of the ligaments in this position rotary and slight lateral motion of the knee is allowed in semiflexion. Hence if we wish to *test the knee for abnormal lateral mobility*, such as is due to rupture of the lateral ligaments, etc., the test should be made *when the knee is extended*. All except the anterior ligaments are taut in extension, only the posterior crucial and the anterior ligaments are taut in extreme flexion. The powerful crucial ligaments are not relaxed in any position of the joint.

The anterior crucial not only resists hyperextension and anterior displacement of the tibia, but also rotation of the leg inward. The posterior crucial ligament resists forced flexion and posterior displacement of the tibia. The lateral ligaments lie behind the center of the joint, about the junction of its middle and posterior thirds, hence they are taut in extension, relaxed in flexion. In the latter position they resist outward rotation of the tibia. They are not very strong. If pus within the joint escapes into the popliteal space it usually does so through the thinnest part of the posterior ligament, the part below the oblique ligament of Winslow.

When one is in the act of falling backward, or in any direction with the knees bent, an instinctive effort is made to avoid the fall by violently contracting the quadriceps to straighten the knee. *By such a spasmotic contraction of the quadriceps one of four lesions may be caused:* (1) fracture of the patella; (2) rupture of the ligamentum patellæ; (3) rupture of the quadriceps tendon; (4) dislocation of the patella.

**Fracture of the patella** is the commonest of these. The fall of the patient is only indirectly the cause of the fracture and it may be the result. In a fall on the bent knee, when the hip is also flexed, the tubercle of the tibia and not the patella comes in contact with the ground. In some cases, however, the patella is broken by direct violence as by a blow or fall directly on the bone. In over 80 per cent. of cases the fracture is *due to muscular action*. The *line of fracture* is quite uniformly *transverse* when due to muscular action, and usually at or just below the center of the bone. Fractures due to direct violence may be transverse, oblique, comminuted or even longitudinal. Another important difference lies in the fact that *in direct fractures* there may be *little or no separation* of the fragments, *in indirect fractures* there is usually some and often *considerable separation*. This *separation depends upon* the amount of *effusion* into the joint, combined with the *transverse laceration of the lateral patellar ligaments*. The influence of the latter is seen in direct fractures, in which, though there may be considerable effusion, there is little or no separation, for the lateral patellar ligaments are practically intact. Again in fractures due to muscular action the lateral patellar ligaments are more or less extensively torn, but the *separation disappears or may be easily overcome if the effusion is gotten rid of*. The pull of the quadriceps tendon is not an important factor in the separation until later on, after atrophy of the muscle occurs.

The rupture of the lateral patellar ligaments and the failure of bony union are explained by the *mechanism of fracture by muscular action*. (Fig. 107.) In the semiflexed position, in which the knee is usually placed when the violent contraction of the quadriceps occurs, only the middle of the back of the patella rests on the trochlear surface of the femur, the upper and lower ends of the bone being unsupported. Its vertical axis is in line with the taut ligamentum patellæ, while the line of action of the violently contracted quadriceps muscle is nearly at

right angles to this axis. The *patella* is thus *broken as one would break a stick over the knee*. The bone gives way first and, the force continuing, the fragments are separated and the tear extends a variable distance into the lateral patellar ligaments, on either side of the line of fracture. The *periosteum and tendinous fibers* in front of the patella stretch a certain distance but, if the fragments are pulled further apart,

FIG. 107.

they give way and curl back in front of one or both fractured surfaces. This interposition of fibrous tissue between the fragments prevents the bony union of these surfaces and often prevents crepitus when the surfaces are rubbed together. This is the reason why treatment by open operation, in this the commonest variety of fracture of the patella, is in such favor, as it alone assures bony union. In direct fractures I have secured bony union without operation and this result is by no means rare. As Morris says, a fracture of the lower and non-articular end of the patella without injury of the synovial membrane is an anatomical possibility, provided the amount of separation is slight. In such a case the fat behind the lower end of the patella saves the synovial membrane from injury. The patella, which is a sesamoid bone developed in the quadriceps tendon, does not ossify until the end of the second year and may be congenitally absent. Nearly all the arteries around the joint furnish blood supply to it.

**Rupture of the ligamentum patellæ** is rare. Exceptionally the tendon is torn from its insertion into the tubercle of the tibia, and rarely the tubercle is avulsed with the tendon.

**Rupture of the quadriceps tendon** above the patella is more common, but rare in comparison with fractures of the patella. It results

from a violent muscular contraction, sometimes from a slight one when the muscle is diseased. Above the patella a well-marked depression appears which is occupied by a blood clot. Rupture of the tendon or ligament is treated by aseptic suture. In these three forms of injury the ability to extend the knee is lost or impaired.

**Dislocation of the patella** is rare. The commonest form is the outward dislocation which may be complete or, more often, incomplete. It may be caused by a blow on the prominent inner border or, more commonly, by a violent contraction of the quadriceps muscles. It occurs most often in the extended position of the limb, when the front of the capsule and the ligaments of the patella are most lax. The line of action of the quadriceps, in the axis of the thigh, is not the same as the axis of the patellar ligament, in the axis of the leg. When therefore the quadriceps contracts, the patella, which lies at the angle of meeting of these two axes, is pulled outward, as the muscle and ligament tend to form a straight line. In knock knee therefore the tendency to outward dislocation is increased by the greater angle between the muscle and the ligament. The outward dislocation of the patella is resisted by the prominent outer margin of the trochlear surface of the femur and by the internal expansion of the quadriceps. The latter may remain intact in an incomplete dislocation, but must be ruptured to allow a complete outward dislocation. In the latter the patella is displaced to the outer side of the external condyle and usually lies with the inner border directed forward and the posterior surface inward. The next most common form is the so-called edgewise or vertical dislocation of the patella. In the commoner variety of this form the inner border rests in or near the bottom of the trochlear groove with the outer border projecting forward and the anterior surface looking inward. The opposite displacement is nearly as common. Muscular action, not always violent, seems to be the most common cause of this form also, but it may be due to a blow on the inner edge of the bone. Inward dislocations are rare.

The semilunar cartilages are attached by their peripheral surfaces to the capsule and lateral ligaments of the knee. In effusions into the joint one sees a groove in the bulging capsule on either side of the lower end of the patella, due to the lateral patellar ligaments and to this attachment of the semilunar cartilages, which incompletely divides the synovial cavity into an upper larger and a lower smaller portion. Dislocation of one or the other of the semilunar cartilages occurs as a rule from a twist of the leg in the semiflexed position of the joint. In flexion and extension of the knee the cartilages move with the tibia, but in rotation one or the other disc is held firmly between the two bones while the other is liable to slip between them. Thus in rotation outward, performed chiefly by the biceps, the external meniscus is held closely between the outer condyle and the tibia, as these two are pressed together by the biceps. This increases the gap between the internal condyle and the tibia into which the internal disc is liable to slip. Similarly in internal rotation the outer disc is the one liable to dis-

placement. Hence the rule that *dislocation of the internal disc occurs from an outward twist of the knee, that of the external disc from an inward twist.* The internal disc is dislocated more than three times as often as the external and the left knee is affected nearly three times as often as the right. This may be partly accounted for by the fact that the external cartilage is smaller, rounder and more movable than the internal, and is attached partly to the posterior crucial ligament, and thereby to the femur. The popliteus tendon which grooves its outer surface, postero-externally, may also help to hold it. The *dislocated cartilage is torn from its attachment to the tibia, usually at one end, and is at times pulled into the joint during flexion and rotation, where it becomes pinched and locked between the two bones, giving rise to a sudden pain and fixation of the knee in the flexed position.* On palpating the line of the joint we may *feel a gap*, when the disc is displaced into the joint, or a marked *ridge* when it is displaced laterally. The *displacement can usually be reduced by extension followed by sudden flexion and rotation; but an operation is often required to effect a cure, by removing the loose portion or suturing it in position.*

The **synovial membrane** of the knee is the most extensive and complicated in the body.. It extends as a *pouch between the quadriceps and the front of the femur* for about an inch above the trochlear surface of the femur and the upper end of the patella. Above the pouch is a bursa (subcral) between the quadriceps and the front of the femur, over an inch long vertically, which communicates with the pouch in 70 per cent. of cases in children and 80 per cent. in adults. The partition varies from a complete septum to a mere trace. In the extended position therefore, we may find a *synovial cavity*, continuous with the joint, *over two inches (5 to 8 cm.) above the patella* or the trochlear surface of the femur, so that a wound or incision at this level may practically open into the joint in a majority of cases. In extension the pouch is supported by the subcureus while in flexion it is somewhat drawn down. *In case of effusion into the joint the pouch and bursa appear as a median prominence or, if separate and both are filled with effusion, as two prominences above the patella.* In this condition of effusion into the joint *the patella is raised from the trochlear surface of the femur, on account of its connection with the anterior part of the capsule, and is said to "float."* By sudden pressure on the patella the latter is made to strike the femur producing a *click*, which is useful as a diagnostic sign of fluid in the joint.

The attachment of the posterior crucial ligament to the posterior ligament divides the synovial cavity, posteriorly, into an inner and an outer condylar recess. The upper third of the ligamentum patellæ is separated from the synovial membrane by a pad of fat, the lower two thirds from the tibia by fat and a bursa. The synovial membrane is remarkable for the number of *fringes* from its inner surface, especially about the patella. Laceration of these fringes, followed by their infiltration with blood and their subsequent exfoliation, gives origin to some of the "*loose bodies*" in the knee joint. The organization of an

intra-articular clot or of fibrinous deposits in the joint may also produce similar "loose bodies."

**Synovitis** from injury or exposure to cold is more frequent in the knee joint than elsewhere, owing to its superficial and exposed position. The floating of the patella and the bulging of the sac above at the sides of the patella have already been referred to (see page 458). *In chronic inflammation* of the knee joint the latter almost always assumes the **flexed position** which may be partly *explained as follows*. (1) The capacity of the joint is increased on moderate flexion, being greatest in flexion to 25° and least in complete flexion. The knee therefore assumes the flexed position to diminish the tension, which causes pain from pressure on the nerve endings. (2) The irritation of the sensory nerves of the joint causes a reflex contraction of the muscles, which fix the joint and prevent motion, as the latter is painful. The flexor muscles are more powerful and more favorably placed for acting and hence the joint is flexed. The flexed position, at first maintained by muscular action, is later on fixed by fibrous or bony ankylosis.

**Excision of the knee** is sometimes required in chronic tubercular disease (white swelling), or in case of a knee ankylosed from any cause in a strongly flexed position. Through an *incision* from the hind part of one condyle to that of the other, curving below the patella the joint is opened and the upper flap turned up. The internal saphenous vein and nerve need not be divided. When there is ankylosis with marked flexion we may remove a wedge-shaped segment of bone with the base anteriorly. In this way no undue traction is made on the popliteal vessels. *In sawing the femur* the section should be parallel with the normal joint surface, not at right angles with the shaft. If not properly sawn knock knee or bow legs may result. Both bones are best sawn from before backward. With reasonable care there is no danger of wounding the popliteal vessels, although there is more danger while sawing the tibia than the femur (see p. 452). The operation should be done in such a way that the *limb* may be *absolutely straight*. In subjects who have not attained their growth the *greatest care* must be taken to do no damage to the epiphyseal line, for the greatest amount of growth in length occurs at this end of both bones. The level of the epiphyseal line of the femur has already been given (p. 449). The lower femoral epiphysis unites with the shaft about the twentieth year. The limits of the *upper tibial epiphysis* are indicated by a horizontal line just below the tuberosities, behind and laterally, so as to include the attachment of the semimembranosus and the facet for the fibula. In front it slants down on each side to meet just below the tubercle, which is included in the epiphysis. It unites with the shaft in the twenty-first or twenty-second year. **Arthrectomy** of the knee has replaced excision to a large extent, and is preferable in suitable cases.

**Disarticulation** at the knee may be done by (1) lateral flaps (Stephen Smith), (2) an elliptical incision or (3) a long anterior flap. The best method is the first. In the method by a long anterior flap there is danger of sloughing of the flap. All methods have the disadvantage

of leaving a large surface of cartilage which has little or no reparative action. Hence I prefer Gritti's method, in which the lower surface of the condyles and the articular surface of the patella are sawn off and the sawn surfaces brought together. The patella with the tough skin covering it then forms the lower end of the stump.

**Fractures of the Lower End of the Femur.**—Besides the fractures of the shaft above the condyles (see p. 448) we find : (1) intercondyloid fractures, (2) fractures of either condyle and (3) separation of the epiphysis. In (1) *the line of fracture* between the condyles follows the intercondyloid notch in a sagittal plane and forms a T with the fracture separating both condyles from the shaft. (2) Fractures of either condyle are not common and may be due to avulsion through the lateral ligaments, direct violence or the pressure of the head of the tibia. The *fracture line* runs into the intercondyloid notch. (3) **Separation of the lower epiphysis** of the femur occurs *more often than that of any other*. It is *commonly due to great violence*, acting especially in extending or abducting the knee. The separation here, as elsewhere, takes place between the cartilage and the shaft. The *periosteum is freely stripped up* from the shaft, but remains attached to the epiphysis. The epiphysis is commonly *displaced* forward and to one side, usually the inner. The injury is frequently compound. Direct reposition has sometimes failed, owing to the presence of prominent lips on the epiphysis and to the tension of the periosteum. In such cases operative reposition, through an external incision, has given good results.

**Fracture of the upper end of the tibia** is *not common*, less so than that of any other part of the bone. It may be *due to severe direct or indirect violence*, and *the line of fracture* may or may not involve the articular surface. Owing to the proximity of the knee joint, which is often involved directly or indirectly, an *effusion occurs* within the joint. *Separation of the upper epiphysis of the tibia* has been observed in a few cases. The upper end of the tibia and the lower end of the femur are *favorite situations for osteosarcoma*.

## THE LEG.

As the limits of this region we may take the level of the tubercle of the tibia above and that of the base of the malleoli below.

**Landmarks and Surface Markings.**—The anterior tibial border or "shin" can be felt throughout its entire length. It is sharp and curved outward above; rounded, less prominent and curved inward in its lower third, where it ends in front of the internal malleolus. The *inner border* can also be felt from the tuberosity above to the malleolus below. The *internal surface*, between these two borders, is subcutaneous except above, where it is covered by the tendinous insertion of the sartorius covering those of the gracilis and semitendinosus. Although *the head of the fibula* is easily felt its *shaft* is buried by the overlying muscles in its upper half. In its lower half it becomes pal-

pable, especially in the lower four inches, where the malleolus and the triangular surface above it are subcutaneous. This subcutaneous area lies between the peroneus tertius and brevis. The fibula is well behind the tibia, so as to be posterior to the plane of the posterior border of the latter. *Anteriorly*, between the two bones, we can see the outline of the tibialis anticus internally, and that of the narrower and more external extensor communis digitorum can be made out when in action. The groove separating these muscles is quite distinct in muscular subjects and forms the best guide to the anterior tibial artery. In the lower third of the leg the tendon of the extensor longus pollicis comes to the surface and can be felt between these two muscles. *Posteriorly* the prominence of the calf is mainly formed by the gastrocnemius, whose two heads are conspicuous when one stands on the toes. In this position it is seen that the inner head is larger and longer. In the same position the *Achilles tendon* stands out in prominent relief from about the middle of the leg to the heel. The soleus comes to view on either side of this tendon but more especially externally where it is less covered by the gastrocnemius.

**Topography.**—The course of the anterior tibial artery is indicated by a line from a point midway between the head of the fibula and the prominence of the outer tuberosity of the tibia to the middle of the front of the ankle joint. The posterior tibial artery runs from the bifurcation of the popliteal, at the center of the lower end of the popliteal space, opposite the lower end of the tubercle of the tibia and about two inches below the joint, to the mid-point of a line from the tip of the internal malleolus to the lower and inner corner of the prominence of the heel. At this point the artery bifurcates into the two plantar arteries. About an inch, sometimes less (15 mm.), below its upper end the posterior tibial gives off the peroneal artery, which runs along the inner border of the fibula to about an inch above the ankle joint, where it gives off the anterior peroneal.

The internal saphenous vein, arising from the venous arch on the dorsum of the foot, runs in front of the internal malleolus and thence just behind the internal border of the tibia to the level of the knee, where it lies just behind the internal condyle. The short saphenous vein passes behind the external condyle and thence up the back of the leg to the lower part of the ham where it perforates the deep fascia. Both the internal and external saphenous veins, but more especially the former, are visible beneath the skin unless the subcutaneous fat is very abundant. Both of the saphenous veins and of the tibial arteries are accompanied by nerves of the same name.

The skin of the leg, especially anteriorly, is more adherent to the deep fascia than that of the thigh. Thus in circular amputations it is necessary to dissect up the skin flap and not merely to retract it. Owing to the conical shape of the leg it may be difficult or impossible to dissect back this skin flap without splitting it on one side in the form of a cuff. The subcutaneous tissue of the leg, especially in front, contains comparatively little fat, so that the skin over the inner sur-

face of the tibia lies *nearly directly on the bone*. The skin is here exposed to blows and kicks, which produce a degree of pain, bruising or cutting far in excess of what a similar violence would produce elsewhere. *Ulcers and eczema*, as the result of varicose veins, are common in front of the leg and run a very chronic course. Ulcers over the bone may expose the latter, lead to disease of its surface and result in scars that are adherent to the bone.

In the subcutaneous tissue lie the superficial veins, nerves and lymphatics. The *long saphenous vein* is not infrequently double in the leg, the second trunk lying behind the regular course of the first trunk (see p. 461), that is further behind the internal border of the tibia. Most of the *superficial lymph vessels* accompany the long saphenous vein and the majority of them are in front of it, while the *long saphenous nerve* usually lies behind and deeper than the vein. A few superficial lymph vessels accompany the short or external saphenous vein to the small popliteal nodes. The latter lymph vessels and the *short saphenous vein and nerve* are covered by a duplication of the deep fascia so that they are not strictly in the subcutaneous tissue. The *musculo-cutaneous nerve* perforates the deep fascia near the septum between the peroneal and extensor muscles at the upper end of the lower third of the leg. Thence it runs downward and inward in the subcutaneous tissue, so superficially that it is easily palpable, or even visible in thin subjects.

The **deep fascia** closely invests the leg and in its upper third is adherent to the underlying muscles. Although it is attached to the anterior and internal borders of the tibia it is not wanting over its internal surface, as stated by Tillaux, but continues over this surface more or less adherent to its periosteum. It is *attached to the head and the malleolus of both tibia and fibula and is continuous with the fascia lata above and the annular ligaments and the fascia of the foot below.* Two *septa* passing inward from the deep surface of this fascia, to be attached one to the anterior and one to the external border of the fibula, *enclose a compartment which lodges the peroneal muscles* and separates an anterior from a posterior compartment, externally. These two main compartments are further separated by the bones and interosseous ligament. The *posterior compartment is subdivided* into a superficial and a deep portion by a fibrous septum, the *deep transverse fascia*, which stretches across from the internal border of the tibia to the postero-internal border of the fibula. There is an *aponeurotic expansion* in the substance of the *soleus*, also connected with the internal border of the tibia, which may be mistaken for the deep transverse fascia in cutting through the soleus to expose the posterior tibial artery.

The muscles lodged in the anterior compartment are so compressed within their osseo-aponeurotic walls that they form a protrusion or hernia when the fascia is torn or cut. The *plantaris tendon* has not infrequently been *ruptured*, producing a sudden sharp pain in the calf. The *tendo Achillis* has been *ruptured* during violent exertion, especially at its narrowest and weakest point, about  $1\frac{1}{2}$  inches above its inser-

# PLATE LV.

FIG. 110.

tion or opposite the internal malleolus. But more often it requires tenotomy on account of its contracture. This is best done opposite its narrowest point by introducing the tenotome in front of the tendon at its inner margin to avoid the posterior tibial vessels, and then cutting toward the surface. The *posterior tibial vessels*, however, lie beneath the deep transverse fascia and so far forward that they are in no danger of injury with ordinary care. The *short saphenous vein* is near and usually in front of the outer margin of the tendon and may possibly be wounded. Its accompanying nerve is usually in front of the vein at this point. On section the tendon retracts with its sheath.

**The Vessels.**—The *anterior tibial and the peroneal arteries*, from their close relations with the tibia and fibula respectively, are liable to be injured in fracture of these bones. I have seen gangrene of the foot follow the rupture of the *anterior tibial artery*, in a bad fracture of the tibia. The anterior tibial artery lies on the interosseous membrane in the upper two thirds and in front of the tibia in the lower third. It lies in the first intermuscular interval on the outer side of the tibia, but the whitish line, which is said to indicate this interval on the surface, is usually indistinct and often absent. The *posterior tibial artery* in the upper two thirds of the leg is covered by the inner head of the gastrocnemius and the soleus, the former of which must be retracted inward, the latter divided to reach the artery. The incision is carried three quarters of an inch behind the inner border of the tibia, where the long saphenous vein is to be avoided. The artery is covered by the deep transverse fascia in all parts of the leg, so that this as well as the deep fascia must be divided to expose it. In the lower third of the leg it becomes more superficial, being covered only by skin and fasciae (two layers), and in thin persons it can be felt pulsating in the hollow on the inner side of the tendo Achillis. The *peroneal artery* in the greater part of its course is covered by the flexor longus hallucis, which must be divided or retracted in order to reach it. This artery also is beneath the deep transverse fascia. The peroneal artery, by anastomotic branches at the lower end of the leg, takes the place of the posterior and anterior tibial arteries when the latter are rudimentary or wanting. The *bifurcation* of the popliteal, or sometimes that of the short tibio-peroneal trunk, is where emboli are apt to lodge. If gangrene results, as not infrequently happens, the embolus is probably at the bifurcation of the popliteal, for in this case all three trunks are blocked.

According to Joessel, not only the two regular venæ comites but other veins, anastomosing across the artery, accompany the posterior tibial and increase the difficulty of its ligation. Verneuil thinks that the deep veins of the leg are more often varicose than those of the surface, and that this condition is indicated by aching of the legs and swelling of the feet in those who stand a great deal.

**Varicose veins** are more common in the leg than elsewhere, with the possible exception of the spermatic and hemorrhoidal veins. This fact may be partly accounted for by (1) the length of the veins of the

lower extremity, (2) the action of gravity in resisting their upward flow and in affecting the weight of the blood column which the valves have to support, (3) the loose support of the superficial veins and the lack of the assistance of muscular contraction, and (4) the liability to compression, within the abdomen, of the iliac trunk into which they ultimately enter. *The saphenous veins* are also thin-walled and lie outside of the firm deep fascia, and the long saphenous is liable to be affected by the use of garters. Varicose veins are *enlarged not only in diameter but in length*, hence their tortuous course. *The contour* is irregular and nodular and the nodules, or enlargements of the vein, are found especially just above the valves and at points where the vein is joined by deep veins. At the latter points pressure is exerted from three directions, (1) the weight of the blood column above, (2) the blood current and the resistance of the valve next below and (3) the inflow from the side, the force of which is increased by muscular contraction.

**The Bones of the Leg.**—The tibia bears the entire superincumbent weight. The fibula, besides affording attachment to muscles, plays an important part in the ankle joint and serves as a brace for the tibia, which increases its resistance to lateral strains. The smallest and *weakest part of the tibia* is at the junction of the middle and lower thirds, which accordingly is where most indirect fractures occur.

**Direct fractures** of the shaft of the tibia may occur *at any point* and are often more or less *transverse* so that there is little if any displacement. *If the fibula is broken* at the same time, as it is likely to be, the fractures of the two bones are about *on the same level*. The long, slender fibula, placed as it is on the more exposed aspect of the leg, would apparently be more often broken from direct violence but for its covering of muscles. When one bone alone is broken the other acts as a splint and limits its displacement.

**Indirect fractures** are due especially (1) to a bending or flexion or (2) to violence combined with torsion of the limb. *In (1)* the fracture may be *at any point* and is more or less *transverse* and dentated, hence there is little but angular deformity. *In (2)* the fracture is mostly in the *upper end of the lower third* (the weakest part) and is oblique, *the line of fracture* usually running downward, inward and forward. *The fibula*, which is almost always broken in indirect fractures, breaks as a rule *at a higher level*. The sharp lower end of the upper fragment of the tibia is liable to puncture the skin and compound the fracture from within. In one variety of this form of fracture, first described by Gosselin, the sharp ends of both fragments end in a triangular point and from the bottom of the depression in the lower fragment, corresponding to the point of the upper fragment, a fissure runs spirally downward and often enters the ankle joint.

Owing to the subcutaneous position of the tibia its fractures are *frequently compounded*, from within in indirect fractures, from without or within in direct fractures. On the subcutaneous inner surface and anterior border we can detect even very slight displacements as well as other pathological conditions. In oblique fractures the *lower frag-*

ment is often drawn upward and outward, behind the upper, by the calf muscles and rotated outward by the weight of the foot, which has lost its continuity with the upper leg.

The tibia, more than any other bone, becomes bent in children with rickets. The bowing, "bow-legs," is usually outward, at times associated with or replaced by a forward one. It is caused by a tonic contraction of the muscles and is increased by the weight of the child in walking. It is generally most prominent at the weakest part of the bone, the junction of the lower and middle thirds.

In amputation of the leg in the upper third the "place of election" is a hand's breadth below the knee joint. This point was chosen as giving a convenient length of leg stump for wearing a peg leg; for the knee is then bent and the weight is borne on the tubercle of the tibia. This line of amputation is at or just above the large nutrient artery of the tibia, which therefore does not cause trouble, as it may below. At this level three arterial trunks are met with for the tibio-peroneal trunk bifurcates three inches, or slightly less, below the knee joint. Throughout the leg the two posterior arteries are beneath the deep transverse fascia, or in a duplication of it, the peroneal behind the fibula, the posterior tibial behind the tibia and separated from it by the tibialis posticus and the flexor longus digitorum. The anterior tibial is to be sought in front of the interosseous membrane in the upper two thirds and in front of the tibia below this. In the upper third of the leg amputation by long external flap is the best method, provided care is used to preserve the anterior tibial artery to the end of the flap, and not to bare the bone so high as to run the risk of injuring this artery where it comes forward above the interosseous membrane. Circular amputation is also suitable in the upper half, but less so below, on account of the conical shape and, in the lower third, the lack of a muscular covering. In the middle third amputation by a long posterior flap, including (1) the superficial layer of muscles (Lee) or both superficial and deep muscles (Hey), is a favorite method. Owing to the danger of injury to the covering skin from the pressure of the sharp angle of the shin, after sawing the tibia, this angle should always be bevelled off.

## THE ANKLE.

The limits of this region are artificial and may be placed two fingers' breadth above and below the malleoli.

**Landmarks and Surface Markings.**—The two malleoli are prominent and very distinctly outlined. The external lies opposite the center of the joint, descends lower by half an inch, is slightly less prominent and is half an inch behind the inner malleolus. But as the latter is broader antero-posteriorly the posterior borders of the two are on the same level. The tip of the external malleolus lies opposite the posterior calcaneoscaphoid joint. According to Holden the inner edge of the patella, the internal malleolus and the inner side of the great toe should be in the same vertical plane, a fact to be noticed in setting

fractures. *In front of the ankle the extensor tendons* form a prominence, which is very marked when they are in action in flexion of the ankle. From within outward we can distinguish the tendons of the tibialis anticus (the most superficial), the extensor longus hallucis and the extensor longus digitorum, with the peroneus tertius. On either side of the prominence due to the tendons and in front of each malleolus is a slight depression. Opposite the joint line this depression corresponds to the thin anterior part of the capsule and hence it is replaced by a bulging in sprains, effusions into the joint, tubercular disease of the latter, etc. The *tendo Achillis* forms a marked prominence behind. On either side of it, between it and the malleolus, is a marked furrow. Along the inner furrow, behind the inner margin of the tibia and the back of the malleolus, the tendon of the tibialis posticus can be felt and behind and external to it that of the flexor longus digitorum. Behind the external malleolus the long and short peroneal tendons are palpable, the tendon of the brevis being nearer to the bone.

**Topography.**—The *line of the ankle joint* is half an inch above the tip of the internal malleolus. Opposite the bend of the ankle the anterior tibial artery becomes the *dorsalis pedis* and, with the anterior tibial nerve, lies between the tendons of the extensors longus hallucis and longus digitorum, where its pulsation can be felt. The *line of the artery* is from the middle of the ankle to the proximal end of the interval between the first and second metatarsal bones. In some cases it describes a curve, concave internally. The *posterior tibial artery and nerve* lie behind the internal malleolus, external and a little posterior to the tendon of the flexor longus digitorum. The tendon of the flexor longus pollicis lies still more externally, at the back of the lower end of the tibia, midway between the two malleoli. The posterior tibial artery *bifurcates* into the two plantar arteries opposite the mid-point of a line between the tip of the internal malleolus and the lower and inner corner of the prominence of the heel. The *long saphenous vein* ascends in front of the internal malleolus, the *short saphenous* behind the external malleolus.

The skin covering this part is thin and loosely attached, and rests almost directly upon the bones, with the interposition of but very little subcutaneous tissue. Hence it is readily contused or excoriated, as for instance by ill-fitting splints; and gangrene may result from slight pressure. Thus I have seen gangrene of the skin over the malleolus result from pressure against the bed in sleeping, in the case of an old gentleman who had previously lost a toe from senile gangrene. The subcutaneous connective tissue is abundant only in front and at the sides of the *tendo Achillis*, and only here is there any considerable amount of fat. The deep transverse fascia of the leg is continued down behind the tendons and vessels at the back of the internal malleolus. This fascia and a considerable amount of loose connective tissue and fat separate these structures from the *tendo Achillis*, so that in the tenotomy of the latter there is little or no danger of wounding the posterior tibial vessels.

PLATE LVI.

FIG. 112.

The anterior annular ligament of the ankle and the synovial membranes of the tendons beneath it artificially distended. (Gerrish, after Testut.)

The deep fascia, continuous with that of the leg above and the foot below, is reinforced in front and laterally so as to form firm bands, known as annular ligaments, which bind down and keep in place the tendons in these situations. There are two anterior annular ligaments of which the upper passes transversely between the anterior borders of the tibia and fibula and keeps in place the anterior tendons in the slender lower third of the leg. The lower band begins on the outer side of the calcaneus and splits into two layers, which pass one behind and one in front of the tendons of the peroneus tertius and extensor longus digitorum and then unite at the inner border of the latter. It again divides into two branches, of which the upper goes to the front of the internal malleolus, the lower to the scaphoid and the plantar fascia. This ligament binds down the tendons at the bend of the ankle and prevents them from projecting forward when in action. The lateral annular ligaments connect the back of the malleoli with the calcaneum on the corresponding side and prevent the dislocation forward of the tendons behind these two malleoli. As the result of violence these lateral bands may be ruptured, allowing one or more tendons to be dislocated forward onto the front of the corresponding malleolus. This has happened to the tibialis posticus and peroneus longus, and the latter is more often displaced than any tendon in the body. From the deep surface of the internal annular ligament processes pass forward to bony ridges at the back of the malleolus and the lower end of the tibia, thus forming separate compartments for each of the three tendons here. Thus it happens that the tibialis posticus tendon may be displaced without the other two, which are further from the inner surface of the malleolus.

In passing beneath the two lateral and the lower anterior annular ligament the tendons are provided with separate synovial sheaths, except that there is a common sheath for the two peroneal tendons and for those of the extensor longus digitorum and peroneus tertius. The synovial sheath of the tibialis anticus extends from 5–6 cm. above the ankle joint nearly to the first metatarsal bone; that of the peroneal tendons from 3–4 cm. above the joint to the calcaneo-cuboid joint; that of the extensor longus digitorum and peroneus tertius from 2 cm. above to 4–5 cm. below the joint; that of the extensor longus hallucis from 1 cm. above the joint nearly to the metatarsus; that of the tibialis posticus from 5 cm. above the inner malleolus to the scaphoid, and that of the flexor longus digitorum from 3 cm. above the malleolus to the sole of the foot, where it is crossed by the extensor longus hallucis and communicates with its sheath. These synovial sheaths may become inflamed and filled with fluid and, as at the wrist, this inflammation may be tubercular, with or without the formation of "rice bodies." I have removed a large mass the size of an egg, due to tubercular inflammation of the extensor tendons in front of the ankle. The long tumor, due to an effusion into one of these synovial sheaths, is often constricted where it passes beneath the annular ligament. Inflammation of the sheath of the tibialis posticus may extend to the ankle joint, with which it is in close relation.

Beneath the extensor tendons one finds a second layer of fascia which separates them from the ankle joint and, further forward, covers the extensor brevis digitorum muscle. The *dorsalis pedis artery* and the accompanying anterior tibial nerve lie beneath this second layer of fascia, which must be divided to reach them. In sprains, fractures and dislocations of the ankle these synovial sheaths are apt to be torn and filled with effused blood, and the long-abiding stiffness after such injuries is in part due to these injuries of the sheaths, and the resulting adhesions. Of the tendons about the ankle the *tendo Achillis* and the *peroneal tendons* are quite subject to contracture, the extensor tendons less so and the tendons behind the internal malleolus still less. These contractures of the tendons lead to various deformities of position of the foot, known as club-foot, and the affected tendons require division (tenotomy) to correct the deformity. The rupture and tenotomy of the *tendo Achillis* has already been described (pp. 462-3). The *tibialis posticus tendon* may be divided (1) two inches above the internal malleolus, which is above its synovial sheath and where the tendon is further from the artery than below. The knife is entered close to the inner border of the tibia. (2) It may be divided a little below and in front of the inner malleolus, between the internal annular ligament and the scaphoid bone. The *tibialis anticus* may be divided at the latter point with the *posticus*, or a little above its insertion into the internal cuneiform. The tendon of a sound muscle may be joined to that of a paralyzed one (*tendon grafting*) to prevent a deformity and restore certain movements of the foot. The tendons of the ankle are not infrequently ruptured through violence, especially the *tendo Achillis*.

A bursa is situated between the *tendo Achillis* and the *os calcis*, rising about half an inch above the latter and bulging on either side of the former, when inflamed. Such inflammation, due to excessive walking, an injury or a badly fitting shoe, may simulate ankle joint disease and, if suppurative, lead to caries of the *os calcis*. Bursæ may develop from pressure over the malleoli, especially the external, as in tailors who sit cross-legged.

The *dorsalis pedis artery* from its superficial position is frequently divided in wounds or ruptured in severe contusions while the posterior tibial is well protected from injury by the prominent malleolus, the neighboring tendons and the annular ligament. The *dorsalis pedis artery* may be compressed against the underlying bones and its pulsation may be sought for, to determine the condition of the artery and of the pulse, in senile gangrene and in suspected embolism at the bifurcation of the popliteal.

The ankle joint owes its strength to the strength of the lateral ligaments and the many closely applied tendons, as well as to the mortise and tenon shape of the bony surfaces. The anterior and posterior ligaments are unimportant and so thin that effusion, when it occurs within the joint, is first noticeable in front as a fluctuating bulging, beneath the extensor tendons and especially on either side of them in front of

PLATE LVII.

FIG. 118.

The internal annular ligament of the ankle and the artificially distended synovial membranes of the tendons which it confines. (Gerrish, after Testut.)

FIG. 114.

The external annular ligament of the ankle and the artificially distended synovial membranes of the tendons which it confines. (Gerrish, after Testut.)

the malleoli. This bulging is the more marked because the synovial membrane forms somewhat of a pouch anteriorly and posteriorly. *The bulging in front of the external malleolus* is the best point to open or inject the joint. When the effusion is more marked it may be evident behind, as a bulging of the posterior part of the capsule, which gives rise to fluctuation on either side of the tendo Achillis.

The ankle joint proper is a true hinge joint and normally allows no lateral motion, except passively in extreme extension (plantar flexion) when the narrower part of the upper surface of the astragalus is in the widest part of the tibiofibular mortice. The ankle should be tested for lateral motion with the foot flexed nearly to a right angle, care being taken to grasp the astragalus, and not the calcaneum, by the thumb and fingers directly below and in front of the two malleoli. If the foot is grasped a little lower, over the calcaneum, lateral motion is obtained between the astragalus and calcaneum. *Lateral movement* at the ankle joint indicates disease or injury of the joint. On account of its superficial and exposed position *inflammation of the ankle* not uncommonly results from injury. As the position of the joint does not affect its capacity and the flexor and extensor muscles about balance one another, the foot does not assume any characteristic position when the ankle is inflamed.

Although sprains of the ankle are considered common, Landerer has expressed the opinion that 95 per cent. of so-called sprains are fractures. This is probably literally true if we count as fractures those cases where, instead of a tear of the ligament, a small portion of bone is avulsed at its attachment.

The ankle joint may be dislocated so that the foot is displaced backward, forward, inward or outward. Only the antero-posterior forms are pure dislocations, the lateral forms being associated with fracture of one or both bones of the leg at the ankle.

**Dislocation of the foot backward** is usually due to extreme plantar flexion and the establishment of a new center of motion between the hind margin of the tibia and the astragalus, so that continued movement ruptures the lateral and anterior ligaments, and then the foot is pushed backward or the tibia forward. It may also be due to great force applied to either the foot or leg while the other is fixed. The foot appears shortened in front, where the lower end of the tibia projects prominently and rests upon the scaphoid and cuneiform bones, and the extensor tendons may be felt as tense cords. *The heel is lengthened.* As a result of fracture of the ankle by eversion, partial and even complete backward dislocations are not infrequent, but pure dislocations of this kind are rare. **Forward dislocation** is still more rare. The mode of production and the deformity of the foot are the reverse of the last variety.

**Two forms of dislocation inward** are observed. *In one the foot is much inverted* so that the astragalus can be felt and seen as a prominence below the outer malleolus. In the other there is less or no inversion, but the foot is much adducted so that the toes may even point

directly inward. The latter form may be secondary to a backward dislocation.

The so-called *outward dislocations* represent the deformity in cases of Pott's fracture (fracture by eversion).

**Fractures of the bones of the leg just above the ankle** are produced by eversion or inversion of the foot, aided somewhat by the weight of the body. Both eversion and inversion produce fractures which are very similar. In reference to these fractures it should be remembered that the *tibia and fibula are very strongly bound together* at their inferior articulation, and that this point serves as the fulcrum of a lever, of which the external malleolus represents the short arm and the fibula above the joint the long arm.

FIG. 115.

Diagram of fracture by eversion of the ankle, showing the fractures of the two bones.

**In fractures due to forcible eversion** (Pott's fracture) (Fig. 115), the strain first comes on the internal lateral ligament, which may tear but, owing to its strength, usually tears off the internal malleolus at its base. This allows the further eversion of the foot and the astragalus then presses the external malleolus outward. This is resisted by the strong ligaments of the inferior tibiofibular joint, which suffer violence in the shape of partial rupture or strain, but usually hold the bones together, so that the strain comes upon the long arm of the lever, the *shaft of the fibula, which breaks a little (1-3 inches) above the malleolus*. The upper end of the lower fragment of the fibula is displaced toward the

tibia. The foot is displaced outward and often somewhat backward and everted, the inner malleolus is very prominent and may cause the laceration of the taut overlying skin. The characteristic features are (1) *lateral mobility*, due to some spreading of the tibiofibular joint and to the fracture of the internal malleolus and the fibula above its malleolus and (2) *three points of tenderness*—(a) in front of the tibiofibular joint in the groove between the tibia and the external malleolus, (b) over the base or apex of the internal malleolus and (c) over the fibula just above the malleolus, or 1–2 inches higher.

FIG. 116.

Diagram of fracture by inversion of the ankle. Fracture of the fibula only is represented and at two levels. The dotted lines show a fracture of the fibula some distance above the malleolus, the continuous lines a fracture at the base of the malleolus.

**In fractures due to forcible inversion** (Fig. 116) the external lateral ligament first feels the strain. If the ligament gives way simply a sprain may result, unless the action of the force continues. If the ligament holds, and it commonly does, it pulls the tip of the external malleolus inward, which forces the long arm of the fibular lever outward, until it breaks close above the malleolus, or still higher. The force continuing inverts the foot still further and the astragalus presses against the internal malleolus and breaks off the latter or a longer portion of the lower end of the tibia. The *lateral mobility and the three points of tenderness* are present in this form, but perhaps not so markedly. In this form the injury may stop short with fracture of the fibula, no

injury of the internal malleolus or internal ligament resulting. In fractures by inversion the upper end of the lower fragment of the fibula is displaced outward, unless it is held by the untorn periosteum. To determine the presence and the point of fracture of the fibula an excellent way is to press on the tip of the malleolus, the short arm of the lever, which causes a false point of motion, or at least a point of tenderness, to appear at the upper end of the lower fragment.

Owing to the frequency of these two classes of fractures and the disability following improper treatment they should be carefully reduced and treated. It is especially important to correct the lateral displacement and the eversion, otherwise the gait is painful and imperfect.

The *lower epiphysis of the tibia* is more often separated than the upper. The fibula is usually broken at the same time at a higher level though its epiphysis, which reaches to the level of the tibial articular surface, is sometimes separated in place of a fracture of the shaft. The lower epiphysis of the tibia *includes* the malleolus and the articular surface, and *unites* in the nineteenth year; the *lower epiphysis of the fibula* includes the outer malleolus to the limit of its articular facet and unites about the twenty-first year. Both epiphyseal lines are horizontal and are in contact with the synovial membrane, which extends up between the two bones.

**Excision of the ankle** is rarely done for injury and not often for tubercular disease. Symes' or Pirigoff's amputation often gives a better result. *Bilateral incisions* are usually made over the malleoli; curving forward over the foot in such a way as to lie between the tendons in front and those behind the malleoli. König chisels away the attachments of the lateral ligaments to the malleoli to spare the ligaments. Lauenstein uses a single long external incision, Kocher a transverse external incision, and both of the latter then retract the peroneal tendons backward, divide the external lateral ligaments and fully supinate (invert) the foot, so as to expose both articular surfaces.

## THE FOOT.

**Landmarks and Surface Markings.**—*Along the outer border* of the foot nearly the entire outer surface of the calcaneum is subcutaneous, and we can feel its peroneal tubercle, less than an inch below the malleolus. The short peroneal tendon is above, the long one below it. The *base of the fifth metatarsal bone* is the most prominent landmark on this border and can be felt under all conditions of swelling, etc. The cuboid extends for an inch or so behind it, and it is about  $2\frac{1}{2}$  inches in front of the external malleolus. *Along the inner border* of the foot we can feel the tuberosity of the calcaneum; the sustentaculum tali, 1 inch below the internal malleolus; the *tuberosity of the scaphoid*, about an inch in front of and a little below the internal malleolus; the base and head of the first metatarsal bone, and the sesamoid bones on the plantar surface of the latter. The tuberosity of the scaphoid is the

best landmark on the inner border and can be felt even when the foot is much swollen. In such conditions the head of the metatarsal bone is not plainly palpable, hence it is well to know that the *first tarsometatarsal articulation* is 3 cm. in front of the tuberosity of the scaphoid and 2 cm. in front of the inner end of a line drawn transversely across the foot from the base of the fifth metatarsal bone.

**Topography.**—The mediotarsal joint, *i. e.*, the joint between the astragalus and calcaneum posteriorly and the scaphoid and cuboid anteriorly, commences internally just behind the scaphoid tuberosity and externally midway between the tip of the external malleolus and the base of the fifth metatarsal bone. The *joint line* is transverse with a slight sinuosity, convex forward internally and concave forward externally. The position of the first tarsometatarsal joint has already been indicated, that of the fifth lies just behind the prominent base of the fifth metatarsal bone. The *tarsometatarsal joint line*, between these two ends, is *interrupted* by the mortising of the second metatarsal bone between the internal and external cuneiform. The line of its articulation with the middle cuneiform is 1 cm. behind that of the first joint. The *metatarsophalangeal articulations* are about one inch behind the webs between the corresponding toes, the proximal and part of the middle phalanges being buried in the web. The gap between the internal malleolus and the tuberosity of the scaphoid is filled by the inferior calcaneoscapheoid ligament and the tendon of the tibialis posticus beneath it.

On the outer part of the *dorsum* of the foot the fleshy mass of the *extensor brevis digitorum* can be felt beneath the tendons of the *extensor longus digitorum*, where it can be seen when in action. It fills the gap between the front of the astragalus and the calcaneum. The course of the *dorsalis pedis* artery has been given above (see p. 466); it is crossed by the inner tendon of the *extensor brevis* muscle.

The *plantar arteries* start at the bifurcation of the *posterior tibial*, midway between the inner malleolus and the inner border of the heel. Thence the smaller branch, *the internal plantar*, follows a line to the middle of the plantar surface of the great toe. *The course of the external plantar* is obliquely across the sole to a point a little internal to the base of the fifth metatarsal bone, and thence obliquely inward across the bases of the metatarsal bones, covered by the *interossei*, to the back of the first interosseous space, where *its arch is completed* by anastomosing with the communicating branch of the *dorsalis pedis*. By means of this arch the anterior and posterior tibial arteries anastomose. In *wounds of the plantar arch*, which are serious on account of its depth beneath many important structures, the ligature of both tibial vessels, at or just above the ankle, would not arrest the hemorrhage without fail, for the *peroneal artery* would bring blood to the arch through (1) the anastomosis of the anterior peroneal with the *external malleolar branch* of the anterior tibial and the *tarsal branch* of the *dorsalis pedis*, and (2) the anastomosis of its terminal branch with the *internal calcaneal branch* of the *external plantar artery*. In fact,

however, elevation and pressure will check most hemorrhages of the foot.

The skin of the dorsum and inner aspect of the foot is thin and movable, that of the sole is dense and thick where it normally comes in contact with the ground, *i. e.*, under the heel, the outer border, and the distal ends of the metatarsal bones. The skin on the dorsum is readily excoriated. The skin of the foot becomes *thick and callous* wherever it is exposed to undue pressure. Beneath the abnormal thickenings *bursæ* may develop.

The subcutaneous tissue on the dorsum is lax and abundant so that great swelling occurs from inflammation, and oedema and general dropsy are often first evident here. This tissue is very *thick and dense on the sole*, connecting the skin closely with the fascia and enclosing the fat in little spaces, as in the palm and the scalp. Hence the *skin of the sole does not gape* on being incised, so that exploratory incisions must be longer than otherwise and strongly retracted, to expose foreign bodies, etc. It is most abundant on the sole, where the pressure is greatest, and in those who walk most, and may even reach 2 cm. in thickness beneath the heel, so that it forms a veritable cushion that must diminish the effect of contusions and falls. Owing to its density *inflammation* in it extends with difficulty and can produce *little swelling but much pain*, especially as the skin of the sole is well supplied with nerves and is very sensitive, much more so than that of the dorsum.

In the subcutaneous tissue on the dorsum many *superficial veins* are visible. They form an arch, concave toward the ankle, from the ends or sides of which the internal and external saphenous veins arise. In varicose veins of the leg these veins of the dorsum are often involved. The internal and external saphenous and the musculocutaneous nerves are in the same subcutaneous layer. "*Perforating ulcer*," a peculiar affection, occurs generally at the points of pressure, and is often attributed to trophic disturbances in certain nerve lesions, like locomotor ataxia, etc. *It appears usually as a sinus* leading to bone, into a joint, or through to the dorsum, and often heals with rest.

The fascia of the dorsum consists of *two layers*; the more superficial one is continuous with the annular ligaments and covers the long tendons; the deeper forms a sheath for the extensor brevis muscle and covers the dorsalis pedis artery. They are thin and of no surgical importance. On the contrary the deep fascia of the sole or plantar fascia is very important and, like the palmar fascia, *consists of three parts*, a dense strong central portion and two thinner lateral portions. The outer portion is however very strong and forms a firm band between the calcaneum and the fifth metatarsal bone. The central portion is stretched like a bow-string between the two ends of the longitudinal arch of the foot, the inner tuberosity of the calcaneum and the heads of the metatarsal bones, where it divides into slips for the toes similar to those for the fingers in the hand. Hence the plantar fascia, especially its central portion, is an *important factor in maintaining the longitudinal arch of the foot*, the sinking of which, in flat foot, necessi-

tates a marked yielding of this fascia. *Talipes carus*, in which the arch is much raised, depends largely or entirely upon a contraction of this fascia. In this condition and in *talipes varus*, in which this fascia is often contracted and the arch correspondingly raised, the fascia is divided subcutaneously by a tenotome to cure the deformity. This division is best made about one inch in front of its posterior attachment, in its narrowest part, where the knife, entered from the inner side, is behind the external plantar artery. This fascia bears the same relation to inflammation and abscess as the palmar fascia in the hand. Similarly two intermuscular septa pass from its deep surface, where it joins the lateral portions, to the plantar aspect of the bones and the interosseous fascia. Three muscular compartments are thus formed, of which the central one is the larger and deeper and contains the majority of the muscles and tendons and the plantar vessels and nerves. These intermuscular septa are too feeble to affect the course of a deep plantar abscess to any great extent.

The posterior tibial nerve bifurcates a little above the artery, and the internal plantar nerve, unlike the corresponding artery, is the larger of the two. In its distribution the internal plantar nerve corresponds closely with that of the median in the hand, the external plantar with the ulnar.

The bursa in the subcutaneous tissue over the first metatarso-phalangeal joint, when enlarged, constitutes a bunion. This is usually associated with a deformity of the great toe (*hallux valgus*), generally due to improperly shaped or too short shoes, which force the great toe outward and render its metatarso-phalangeal joint very prominent internally. The overlying skin becomes thickened and indurated and the bursa, pressed between this thickening and the projecting bone, becomes inflamed. If it suppurates it often opens both superficially and into the joint. The latter then becomes disorganized and requires resection. In this operation it must be remembered that the outwardly displaced extensor tendon of the toe and the inner part of the fibrous capsule of the joint have probably both become contracted and shortened. Holden describes the frequent occurrence of a large irregular bursa between the tendons of the extensor longus digitorum and the underlying prominent end of the astragalus, which sometimes communicates with the mediotarsal joint. Bursæ may develop almost anywhere from pressure, as beneath the points on which the foot rests in the various forms of club foot.

The numerous fine lymphatics of the sole pass to the borders of the foot, especially the inner border, and to the dorsum, where the main lymph vessels are found, particularly on its inner side. Thence they run along the inner side of the leg with the internal saphenous vein, and pass mostly to the inguinal nodes. Some run up the outer side of the leg, or with the short saphenous vein, but most of the former cross over the popliteal space, or the front of the leg, to join the inner vessels, so that only a few enter the popliteal nodes. Hence in inflammation on the dorsum and inner border of the foot lymphatic enlarge-

ment will involve the inguinal nodes, while inflammation on the outer border may affect either the inguinal or popliteal nodes. Lymphangitis most often follows lesions of the dorsum and inner border.

The foot is arched in two directions, longitudinally and transversely. These arches are due to the shape of the bones and are maintained by ligaments and, to a less extent, by the tendons and short muscles of the sole.

The longitudinal arch, the more important of the two, consists of two piers on the ends of which the foot rests, *i. e.*, the heel and the heads of the metatarsal bones. In addition the foot is supported or buttressed by its outer border. The middle of the inner border and the inner part of the sole is raised from the ground by the inner and more curved portion of the arch, which is thus known as the *instep*. On account of this difference of the two borders the arch is divided into two parts having a common posterior pillar, the calcaneum and the hind part of the astragalus. The anterior pillar of the outer and flatter arch is formed by the cuboid and the two outer metatarsals; the anterior pillar of the inner and more curved arch is formed by the scaphoid, cuneiform and three inner metatarsals. The outer arch forms a buttress to steady the more elastic inner arch. The anterior pillars composed of a number of small bones and their joints are very elastic and springy, giving the elasticity to the gait. The posterior arch, consisting of only one joint and two bones, astragalus and calcaneum, is solid in order to support the greater part of the weight of the body, and inelastic to give a firm attachment to the calf muscles. The difference in the two arches is seen in jumping from a height. When we alight on the heels the jar is felt throughout the body, but when we alight on the ball of the foot the elasticity of the anterior pillar of the arch absorbs, so to speak, all the jar. The astragalus, or more especially its head, serves as the keystone of the arch, but, unlike keystones in ordinary arches, it is not wedge-shaped, it is mobile and it only imperfectly supports and receives support from the two pillars.

The transverse arch is most marked near the tarsometatarsal joints and is due to the wedge shape of the bones. It protects the vessels and soft parts of the sole and, by its yielding in walking, etc., gives elasticity and spring to the foot.

Both of the arches are maintained by ligaments and tendons. The transverse arch is maintained by the transversely directed dorsal, plantar and interosseous ligaments, and by the obliquely directed peroneus longus tendon and, to some extent, the expansion of the tibialis posticus tendon. When the transverse arch is properly maintained the anterior pillar of the longitudinal arch rests upon the heads of the first and fifth metatarsal bones only. If the transverse arch yields the heads of the intervening metatarsal bones receive undue pressure and callosities develop over them. The longitudinal arch is maintained principally by the inferior ligaments of the mediotarsal joint, the long and short plantar and the inferior calcaneo-scaphoid ligaments. The former are

the main support of the outer, firmer and less elastic part of the arch ; the latter is known as the “*spring ligament*” as it is the principal ligament that supports the inner and more springy part of the arch. *It helps to support the head of the astragalus*, part of which rests directly upon it. It in turn is supported by the *tibialis posticus tendon*, which runs in a groove on its under surface and comes into action when the heel is raised and the weight is thrown onto the instep, and therefore when the most strain comes on this ligament in supporting the head of the astragalus and the mediotarsal joint. The *tibialis anticus* is said to support the keystone, but as no keystone can be supported, but only weakened, by traction from above, it can only support it by reason of the fact that the constituents of the arch are connected and supported by ligaments.

FIG. 117.

**Club-foot.**—*The longitudinal arch sometimes yields and flattens out.* This gives rise to one variety of club-foot known as “flat-foot,” in which *the foot is abducted and pronated (everted)*, the sole becomes flat and the patient walks mainly on the inner side of the foot. Some abduction of the foot is necessarily anatomically associated with raising of the outer border, or pronation, for the pronating peronei are also abductors. The impression of the wet sole on a sheet of paper shows no deep concavity along the inner border, as normally, but rather a convexity. (See Fig. 117.) *It occurs particularly in those who stand a great deal and especially in adolescents who are below par, who have grown rapidly and in whom the muscles and ligaments are relaxed and more ready to yield to long continued pressure.* *The inferior calcaneo-scaphoid ligament suffers most* and by its yielding allows the head of the astragalus to be pressed downward, forward and inward, so that the latter, together with the depressed sustentaculum tali and the scaphoid tuberosity, form prominences on the inner border of the foot, which may rest on the ground. The plantar and deltoid ligaments and the plantar fascia also yield, and in time the deformity may be rendered permanent by alterations in the shape of the bones, by contraction of the ligaments that are relaxed and by shortening of the peronei muscles, which are relaxed by the abduc-

tion and eversion of the foot. In this acquired deformity, occurring in the developed foot of adolescents or adults, the affected tarsal bones and articulations suffer abnormal pressure, which often causes severe pain. The latter gives rise to the term "*painful flat-foot*," to distinguish it from a similar deformity without pain, which may be congenital. The acquired deformity is also known as *acquired talipes valgus*, the congenital as *congenital talipes valgus*. The latter is usually associated with some *talipes calcaneus*. The normal foot is not flat at birth.

**Talipes** is a term applied to all forms of *club-foot*, of which there are four primary varieties which may be variously combined with one another. In *talipes equinus* the heel is drawn up by the contraction of the calf muscles so that the patient walks on the bases of the toes. The arch of the foot is often exaggerated. *Talipes equinus* is rarely congenital and results from infantile paralysis of the extensor tendons and other paralytic lesions, as well as from the long continued extended position of the foot, due to faulty splints or the weight of the bed clothes in cases of long illness, etc.

The opposite condition, *talipes calcaneus*, is characterized by dorsal flexion and is due to contraction of the anterior muscles, usually associated with infantile paralysis of the posterior groups. The patient walks on the heel with the foot drawn up. It is rarely congenital and often combined with *talipes valgus* and *pes cavus*.

In *talipes varus* the foot is inverted and hence also adducted, for the same muscles produce both actions. It rarely occurs without some *talipes equinus*, and *talipes equinovarus* or *congenital club-foot* is the commonest form of *club-foot*. It usually originates in an arrest of the foetal development of the feet, resulting in the delayed rotation of the feet and legs, so that the equinovarus position of the feet that is normal in early foetal life persists. A similar deformity may result from infantile paralysis. The deformity is a kind of dislocation inward of the fore part of the foot at the mediotarsal joint, and consists of elevation of the heel, inversion and adduction of the foot and increase of its longitudinal arch, associated with contracture of the plantar fascia. Hence the patient walks on the outside or, in extreme cases, even on the dorsum of the foot. The toes point inward so that one foot is lifted over the other in walking. The os calcis becomes more vertical than horizontal; the head and the elongated neck of the astragalus are rotated downward and twisted inward; and the scaphoid, with the three cuneiform and the three inner metatarsals, are displaced inward, upward and backward. The tarsal bones become much misshapen. The neck of the astragalus is deflected inward from the axis of its body at an angle of  $10^{\circ}$  in the adult,  $25^{\circ}$  at birth and  $50^{\circ}$  in *talipes equinovarus*. The ligaments are contracted on the concave inner side and stretched on the other side. The peroneus longus tendon may slip in front of the external malleolus. In most forms of *club-foot* the contracted muscles require tenotomy, also the plantar fascia when that is contracted.

The chief joints of the foot are the calcaneoastragaloid, the mediatarsal and the tarsometatarsal.

The *principal ligament* of the calcaneoastragaloid joints, from a surgical standpoint, is the massive *interosseous ligament* in the sinus pedis. The lateral ligaments of the ankle, the surrounding tendons, the various calcaneoastragaloid and the external calcaneoscaphoid ligaments help to hold the bones together. This is a double joint, the posterior having a separate synovial sac, the anterior a sac in common with the astragaloscaphoid joint. The *movements* of ab- and adduction and some pro- and supination are allowed. This joint is of practical interest in subastragaloïd amputation, subastragaloïd dislocation and dislocation of the astragalus.

**Subastragaloïd dislocation** involves the astragaloscaphoid and calcaneoastragaloïd joints. The position and relation of the astragalus with the tibia and fibula and the movements in the ankle joint remain normal. In these dislocations the *foot is displaced* either (1) inward, or rather inward and backward, or (2) outward, very rarely (3) backward or (4) forward. In the **dislocation inward and backward** the dorsum is shortened, the heel lengthened, the foot adducted and supinated, the external malleolus and the head of the astragalus are very prominent on the outer side of the dorsum, and the internal malleolus is deeply buried. *The deformity* resembles talipes varus. *The cause* is often forcible inversion and adduction of the foot. In the **outward dislocation** either the outward displacement may be combined with marked abduction of the toes, when the foot turns on the posterior calcaneoscaphoid joint if the bones have not separated there, or the foot may be displaced bodily outward. Hence the dislocation may be incomplete as regards the posterior calcaneoastragaloid joint. When the foot is abducted there is more or less eversion and the head of the astragalus is very prominent on the inner side. In the form with simple outward displacement the inner malleolus is very prominent and approaches the level of the sole. The head of the astragalus projects below and in front of it, while the outer malleolus is buried in the depression above the prominence of the outer surface of the calcaneum and cuboid. The subastragaloïd dislocations are often compounded.

**Dislocation of the astragalus** is a combination of the subastragaloïd dislocation and that of the ankle, and is much more frequent than either of them. It is often compound and either or both *malleoli may be fractured*. The astragalus may be *displaced* antero-posteriorly or laterally. Dislocation outward and forward is the commonest form, inward and forward the next, simply forward or backward rare, and inward is almost unknown. In the **dislocation outward and forward** the head of the astragalus rests on the cuboid and external cuneiform, and is freely movable. *The foot* is adducted, inverted and usually displaced inward so that the internal malleolus is buried, the external is prominent. In the **inward and forward dislocation** the head of the astragalus projects below and in front of the inner malleolus and is

much depressed, as if rotated on a transverse axis. *The foot is usually everted and abducted, but sometimes simply displaced outward.*

The malleoli are brought nearer the sole in almost all cases of dislocation of the astragalus. In addition *the astragalus*, while remaining within the tibiofibular mortise, *may rotate on its antero-posterior axis, sometimes on its vertical axis.* *Dislocation of one or more of the other tarsal and of the metatarsal bones* occasionally occurs, the most frequent being dislocations of the scaphoid, the inner cuneiform or the first metatarsal.

**The mediotarsal joint**, composed of the astragaloscaphoid and calcaneocuboid joints is *the most movable of the tarsal joints and permits ab- and adduction, pro- and supination, and flexion and extension of the fore part of the foot on the back part.* In these movements *flexion is combined with adduction and supination of the foot, extension with abduction and pronation of the foot, owing to the obliquity of the axis of this joint, from within outward and somewhat backward and downward.* This combination is seen in talipes varus and valgus in which, as well as in pes cavus and pes planus, the principal displacement occurs in the mediotarsal joint. In studying the arches of the foot we have seen that *the inferior ligaments of this joint* (the inferior calcaneoscaphoid and the plantar ligaments) are *the principal support of the longitudinal arch.*

Exclusive of that of the ankle there are *six synovial membranes* among the joints of the tarsus and sometimes seven, if there is a separate sac between the cuboid and external cuneiform. *The most extensive* is that between the scaphoid and the three cuneiform bones, which extends forward between the latter to the second and third tarsometatarsal joints and the joints between the second and third and third and fourth metatarsal bones. Hence disease of the bones in relation to this joint would be most likely to extend, while that of the bones near the posterior calcaneoscaphoid joint would be least likely to do so.

*Through each of the three principal joints of the foot that we have named, amputation may be practiced.* In **subastragaloïd amputation** the astragalus is disarticulated from the calcaneum and the scaphoid and *two synovial sacs are opened.* The extremity rests on the astragalus and the operation gives a good result. In **Chopart's amputation through the mediotarsal joint** two synovial sacs are opened. Subsequently, from contraction of some muscles or loss of the point of attachment of their antagonists *the heel may be drawn up* by the calf muscles so that the scar on the anterior face is turned downward, or the inner border of the foot may be raised so that it rests on the outer border. It is not well suited to cases of bone disease and the operation is now seldom practiced. The landmarks have been given for **Lisfranc's amputation through the tarso-metatarsal joint** and *the only difficulty* pointed out, *i. e.*, the backward projection of the second metatarsal bone between the outer and inner cuneiform bones, where its chief bond of union with the tarsus is the interosseous ligament that connects it with the inner cuneiform. **Hey's operation avoids the diffi-**

culty of disarticulating this bone by sawing through it, in the line of the other joints. Neither operation is often indicated or even possible in conditions depending on accident or disease.

Far better than Chopart's amputation are the two following amputations of the foot. In Symes' amputation *the incision* runs from the tip of the outer malleolus vertically downward, then transversely across the sole and vertically up on the inner side to half an inch below the inner malleolus. This brings the end of the inner incision at the same height as the external. The soft parts covering the heel are dissected carefully away from the calcaneum, and *the tough skin of the heel*, accustomed to bearing pressure, *covers the stump* left by sawing the leg bones just above the articular cartilages. The skin of the inner part of the heel flap is supplied by the internal calcaneal branch of the external plantar artery, and it is most important for the life of the flap not to cut off this blood supply, as may be done by carrying the internal incision further back than directed.

Pirogoff's amputation closely resembles Symes' except that *the incision* is carried *a little further forward*; *the calcaneum is sawn through* in the line of incision, or more obliquely; the posterior end of the calcaneum is applied to the under sawn surface of the tibia; and the tendo Achillis is not divided. Owing to the position of the incision *the plantar vessels are divided further forward* than in Symes' operation, so that there is less danger of gangrene of the skin on the inner side of the heel. In *amputation of the great toe* the large size of the head of the first metatarsal bone must be borne in mind, so as to cut the flaps large enough to cover it and bring the line of the cicatrix above the plantar surface, for, as it is one of the anterior ends of the longitudinal arch, this surface is subject to much pressure.

The calcaneum is more often fractured than any of the tarsal bones. By a fall on the heel it may be splintered and crushed, especially in its anterior half, and its vertical diameter may be decreased, so that the sole is flattened and the malleoli are approximated to it. By a forcible contraction of the calf muscles the calcaneum has occasionally been fractured, always behind the astragalus and sometimes only the back part, which attaches the tendo Achillis. The latter is usually ruptured in place of fracture of the calcaneum from muscular violence. The displacement of the fragment is sometimes slight, sometimes extreme,  $4\frac{1}{2}$  inches (Constance). The astragalus alone may be fractured by falls, but the lesion is often associated with fracture of the calcaneum, or at the ankle, etc. Fracture of the other tarsal bones, the metatarsal and the phalanges is commonly due to direct violence. Such fractures are often compound, owing to the scanty covering of soft parts on the dorsum of the foot which are usually contused or lacerated.

The toes very closely resemble the fingers, except in size, and are liable to similar lesions from injury, inflammation, etc., though not so frequently. Dislocation of the proximal phalanx of the great toe is similar to that of the like joint of the thumb in the character of the lesion, the difficulty of reduction and the reasons for this diffi-

culty. A peculiar affection of the toes known as "hammer toe," in which the proximal phalanx is extended while the middle is strongly flexed, is most often found in the second toe, which is normally longer than the others. It is *due to* a contraction of the extensor tendon and of the glenoid and lateral ligaments of the first phalangeal joint.

The cutaneous nerve supply of the lower extremity is shown by Figs. 118 and 119.

Paryses of the lower extremity are common and usually due to a lesion of the cord, hence they involve all or a considerable group of nerves. Occasionally a single nerve trunk is paralyzed by a cord lesion or a lesion of the nerve below its exit from the spinal foramen. This involves a limited area of anaesthesia or motor paralysis. An example of motor paralysis of groups of muscles is seen not infrequently after infantile paralysis.

Paralysis of the anterior crural nerve may be *due to* fractures and tumors of the pelvis, psoas abscess, dislocations of the hip, stab wounds in the groin, and perhaps a partial lesion of the cauda equina. *The patient can not flex the hip*, as in rising from the recumbent position, (iliopsoas and pectineus), or extend the knee (quadriceps). The sartorius is paralyzed, the pectineus partly so, being supplied in part by the obturator. In the parts supplied by the internal and middle cutaneous and long saphenous nerves *sensation is impaired*.

The obturator nerve alone is seldom paralyzed but may be, occasionally, from the pressure of the fetal head or an obturator hernia or from lesions similar to those paralyzing the anterior crural. *The patient can not adduct the thighs or cross the legs (adductors) and outward rotation of the thigh is impaired (obturator externus and adductors).* *Sensation of the cutaneous area supplied is impaired.*

Paryses of the internal or external popliteal alone are not common and are usually due to traumatism below the bifurcation of the great sciatic. *In paralysis of the internal popliteal nerve the patient can not extend the ankle, flex or stand upon the toes (muscles of the back of the leg) or move the toes laterally (short muscles of the sole).* Adduction and supination of the foot is impaired (tibialis posticus). The *sensation in the skin of the sole, the under surface and ends of the toes, and the lower part of the back of the leg is impaired.* *In paralysis of the external popliteal nerve the patient is unable to flex the ankle, abduct or pronate the foot or fully extend the toes (anterior leg muscles and peronei).* Hence the toes drag in walking. Adduction and supination are impaired (tibialis anticus). Only the ends of the toes can be extended by the interossei. *Sensation over the front, outer side and part of the back of the leg and the dorsum of the foot is impaired.*

In paralysis of the great sciatic flexion of the knee is lost (hamstrings), and external rotation of the thigh is impaired (obturator internus and quadratus femoris) in addition to the results of paralysis of both the internal and external popliteal nerves. Paralysis of the great sciatic may be *due to* pelvic tumors. These more commonly cause a neuralgia of the nerve. Paralysis or neuralgia of the individual nerves of the

lower extremity may be produced by similar causes. Hence it must be borne in mind that pain in any part of the lower extremity may be due to lesions at a distance, intra-spinal, intra-abdominal, intra-pelvic, etc.

In the diagnosis of the situation of lesions of the cord, due to disease or fracture, a knowledge of the skin areas and the muscles of the lower extremity supplied by the several segments of the cord is important. For this see chapter on the spine.

## CHAPTER VII.

### THE SPINE.

**Landmarks and Topography.**—The first spinous process that is readily palpable is that of the seventh cervical (*vertebra prominens*) or sometimes that of the sixth cervical. Hence we *begin to count the spines from the seventh cervical*. The first thoracic spine is still more prominent than the seventh cervical. *The third thoracic spine* is on a level with the inner end of the spine of the scapula; *the seventh* with the lower end of the scapula; *the fourth lumbar spine* with the highest part of the iliac crest and the bifurcation of the abdominal aorta; *the second sacral spine* with the posterior superior iliac spine and the center of the sacro-iliac joint, the third sacral spine with the upper border of the great sciatic notch, and the first piece of the coccyx with the spine of the ischium. The umbilicus is on a level with the interval between the third and fourth lumbar spines. The thoracic spines are oblique and overlap one another, the lumbar are horizontal and correspond with the vertebral bodies. *The transverse process of the atlas* is palpable a little below and in front of the tip of the mastoid process, the anterior tubercle of the sixth cervical vertebra (*carotid tubercle*) is felt on a level with the cricoid cartilage. *The bodies of the upper three cervical vertebrae* can be felt through the mouth at the back of the pharynx, the anterior arch of the atlas being on a level with the hard palate.

The spinal column is required to serve many different functions, (1) to bear the weight of the head and upper extremities, (2) to give attachment to the ribs, (3) to serve as the central axis of the body, to connect its upper and lower segments, (4) to diminish the effect of shocks and jars, (5) to allow of varied and extensive movements and yet (6) to provide a solid canal which safely contains the spinal cord.

Corresponding to the increasing weight to be borne by the vertebral bodies, as we pass from the upper end of the spine to the sacrum, we find that *their surface area gradually increases* from above downward. To allow the varied and extensive movements without injury to the delicate cord within, the spine is composed of a number of small articulated segments, the movement between any two of which is not great but that of the spine as a whole is very considerable. More free movement between a smaller number of segments would not only weaken the spine and make it more liable to injury but also expose the cord to compression by being sharply bent.

Of the four antero-posterior curves only two, *the thoracic and sacral*, are present at birth. These are *primary curves*, due to the shape of the bones, and are convex backward to give more room in the thoracic and

FIG. 120.

The spinal column, right lateral view and dorsal view. (GERRISH, after TESTUT.)

pelvic cavities, which they help to form. *The lumbar and cervical curves, convex forward, are principally due to the shape of the intervertebral discs.* They appear when the erect position is assumed and are *compensatory curves* to allow the child to sit or stand erect. Otherwise the head would project forward and a marked dorsal convexity would exist in the thoracic region. This position is seen in the aged, in whom it largely depends upon the shrinkage of the discs, whereby the compensatory curves dependent upon them are flattened, and thus the primary permanent thoracic curve is exaggerated.

The *normal curves* of the spine may be exaggerated so as to constitute the several forms of curvature of the spine.

*Increase of the posterior convexity in the thoracic region is known as kyphosis.* This is almost always due to a tubercular caries of the bodies

of the thoracic vertebrae and is known as "*Pott's disease of the spine*." When the affected vertebral bodies, being destroyed by the ulceration, yield to the pressure of the superincumbent weight the spine bends forward above the seat of the disease thereby *throwing backward the spinous processes* opposite the diseased area. This gives rise to an *angular curvature or hump back*, which is accompanied by an increase of the cervical and lumbar compensatory curves. Hence

FIG. 121.

Diagrams to show lordosis as a compensating curve in hip disease. A; normal spinal curves. The hip is ankylosed in the flexed position; B; the ankylosed flexed hip is straightened by a tilting of the pelvis, indicated by the position of the dotted line and the presence of lordosis.

to avoid deformity in spinal caries the superincumbent weight should be relieved by apparatus or posture. When the disease attacks the cervical or lumbar vertebrae there is no angular curvature, but the normal posterior concavity of these regions is flattened out and the affected part of the spine is rendered stiff. The neural arches and the circumference of the vertebral canal almost always escape.

*The spinal caries is often associated with abscess* which tends to sink in the line of gravity along the spine. Spinal abscesses in the thoracic or lumbar region tend to enter the sheath of the psoas muscle, in the former region after passing beneath the internal arcuate ligament. They are *the common cause of psoas abscess*. If the curvature is extreme, or comes on rapidly, the front of the cord may be pressed upon by the projection at the back of the vertebral bodies and *motor paralysis results*. More often the cord symptoms are due to the pressure of inflammatory thickenings, deposits or abscesses which may subside from general treatment; but if degenerative changes in the cord appear the spinal canal should be opened to remove

the cause of pressure. In recent years *angular curvatures* of the spine have been *successfully treated by forcible straightening*. In severe cases the chest becomes much distorted and the lower ribs, resting on the ilium or sinking into the pelvis, obliterate the iliocostal space.

**Lordosis** is *an increase of the forward curve*, as in the lumbar and cervical regions. It is most marked and *most often observed in the lumbar region*. It is *almost invariably a compensatory curve* instinctively assumed to keep the center of gravity from being advanced too far and to allow the patient to stand erect. Thus in obesity, pregnancy, angular curvature, congenital dislocation of the hips, and in *hip disease* with flexion of the femur it is present as a compensatory curve. The latter condition is *its commonest cause*. The hip being held or ankylosed in a flexed position, the patient is only enabled to straighten it by a rotation of the entire pelvis by which its upper end is moved forward, which increases the lumbar curve. This is seen in examining such a patient in the supine position. When the affected extremity is extended the lumbar spine is arched forward, when it is flexed to the angle in

which it is ankylosed the lumbar curve is normal, and when it is further flexed the curve is straightened and the lumbar spines press the hand against the table.

**Scoliosis or lateral curvature** may also be said to be *an exaggeration of a normal curve*, for very few are without a slight lateral spinal curve usually to the right in right-handed persons. Scoliosis also *may be a compensatory curve*, compensating the lateral tilting of the pelvis which accompanies an inequality of the length of the legs. It may be due to chronic empyema, or the extensive resection of several ribs to cure it. *More often it is an idiopathic condition* whose etiology we really do not know in many cases. It occurs in children, most often in girls, in whom the muscular development and general condition are below par. A faulty attitude in study, etc., has been thought to favor it. As the *principal curve*, in the upper thoracic region, is *usually convex to the right* in right-handed persons, unequal muscular action is thought to be a causative factor. There are of course compensatory curves in the opposite direction in the lumbar and cervical regions to allow the erect attitude. When the lateral curve has reached a certain degree *the vertebral column begins to rotate on a vertical axis* so that the spines turn *toward the concavity of the curve*, for some unknown reason. This brings the spines nearer the median line so as to diminish the appearance of the curve as indicated by them. It also *carries the ribs backward on the right and forward on the left*, so that the right chest is full and prominent posteriorly but flattened anteriorly, while the left chest is prominent in front but its ribs are crowded together and its capacity is diminished. In time the vertebrae, muscles and ligaments become atrophied and contracted on the concave side, stretched on the convex side.

The spinal canal is completed posteriorly by the fusion of the laminae, or neural arches, at the root of the spinous processes. Each half of the neural arch is formed from a separate ossific center. Failure of this fusion causes a posterior median defect of the laminae and spines which is seen in spina bifida. This is most common in the lumbosacral

FIG. 122.

Diagram to show lateral curvature of the spine. The primary curve is to the right in the thoracic region, the compensatory curves in the opposite direction in the cervical and lumbar regions. The vertebral spines are shown rotated toward the concavity of the curve.

or sacral regions, for here the neural arches are last ossified. Other imperfections of development are often associated with spina bifida.

**Spina bifida** is a congenital defect of the vertebral canal through which some of its contents protrude, *i. e.*, (1) the membranes alone (*spinal meningocele*); (2) the membranes with the cord or, generally, the nerve trunks of the cauda equina, which usually adhere to the posterior wall of the sac (*meningomyelocele*); (3) the latter condition with a sac-like dilatation of the central canal of the spinal cord (*syringomyelocele*). The second variety is the most common, the first, the next, and the third the rarest. In all forms *the sac is filled with cerebrospinal fluid*, almost always from the subarachnoid space (*i. e.*, in the first two forms). Hence the sac, which forms a median dorsal tumor, is more tense in the upright position and on crying. Pressure may return some of the fluid and, by increasing the pressure within the spinal canal, may result in causing irregular muscular movements or even convulsions.

The twenty-three **intervertebral discs** make up nearly one fourth of the length of the spine, hence the height of the body is appreciably decreased from their compression on long standing or sitting, and in old age from the shrinkage of the discs. It is owing to the discs that the movements of the spine are permitted, and these movements are most free where the vertebrae are smallest or the intervening discs thickest, *i. e.*, in the cervical and lumbar regions respectively. Therefore movement is most free where the spinal canal and cord are the largest, where the curve is convex forward, and where there are no bony cavities containing viscera. Free movement in the thoracic region would be a distinct disadvantage to the thoracic viscera. Movement is perhaps most free in the lumbar region, but rotation and lateral motion is freest in the cervical region and extension is as free there as anywhere.

The vertebral bodies with the intervening pulpy portion of the discs really form ball and socket joints, but the *free movements* thereby allowed are *resisted by* the connecting ligaments and *restricted by* the articular processes and in parts by the other processes of the vertebrae. Owing to the more or less horizontal surfaces of the articular processes of the *cervical region* movements in all directions are permitted there. Rotary movements are most free in the atloaxoid joints, flexion and extension in the occipitoatlloid joints. In the *thoracic region* extension is prevented by the overlapping spines and by the shape of the articular processes. The latter limit flexion also, whereas lateral movements, otherwise possible, are prevented by contact between the ribs. In the *lumbar region* lateral movements are limited by the great transverse diameter of the bodies, rotation by the relation of the articular processes.

The *overlapping laminæ* protect the cord from injury in the thoracic region where, owing to the curve, it lies nearer the surface and is most exposed. Between the upper cervical vertebrae the intervals between the narrow laminæ are widest and here the cord can be most easily reached

and wounded by a narrow instrument. Infanticide has been accomplished by pithing the upper cervical cord by a long narrow pin, thrust between the upper cervical vertebrae or between the atlas and the occiput. Again in the lumbar region it is possible to enter the spinal canal by an instrument thrust obliquely upward and forward. This is taken advantage of in lumbar puncture and spinal cocainization. The puncture is made between two lumbar spines below the second lumbar vertebra (usually between the third and fourth), to avoid the cord which extends to the lower end of the first lumbar. To avoid the spines the puncture is made a little ( $\frac{1}{2}$  to 1 cm.) to one side of the median line. In adults the puncture is made opposite the middle of the spine below the interval, to give the needle the desired upward obliquity. The needle is then thrust forward, toward the middle line, and in adults slightly upward, for 2 to 7.5 cm., until the escape of fluid (cerebro-spinal) indicates that its point has entered the subarachnoid space. The canal is entered through the ligamentum subflavum. The possible puncture of one of the nerves of the cauda equina may occur and is shown by the twitching of some of the muscles of the lower extremity.

On account of the number of the joints and ligaments of the spine and the variety and extent of its movements it is readily understood why the spine is liable to sprains. These naturally occur most often where the movements are most free, in the lumbar and cervical regions. The nearness of the head and the transmission of violence, received by it, to the spine may increase the tendency to sprains in the cervical region. Considerable pain and stiffness often persist long after the injury, and these may depend upon a synovitis of one or more of the many vertebral joints. Ecchymosis rarely appears in these cases, for the spine is separated from the skin by many layers of muscles and fasciae.

When the violence applied is more concentrated or more severe fractures or dislocations of the spine are produced. The liability of the spine to these accidents is, to be sure, diminished by its elasticity, due to its curves, its discs, etc., and by the number of its segments. Some have even denied the possibility of dislocation of the spine without fracture, except perhaps in the cervical region, where the small size of the bodies and the more horizontal direction of the articular processes do not offer so much resistance to the separation of the vertebrae. But in many cases the associated fracture is unessential to the production of the dislocation.

**Dislocation** is most common in the cervical region, especially between the fourth, fifth and sixth vertebrae, less common in the thoracic, and exceedingly rare in the lumbar region. The dislocation may be complete or incomplete, bilateral (dislocation by flexion) or unilateral (dislocation by abduction or rotation). In the latter form only one side of the vertebrae is dislocated and the axis of its displacement passes through the other side. But as most dislocations of the spine are partly dislocation and partly fracture, and as it is usually impossible to distinguish between them, furthermore as the effects of the two are

similar, it is best to consider them together. The term *fracture-dislocation* is often applied to all such injuries of the spine.

**Fracture of the spine** may be *due to indirect or direct violence*. Those due to the latter are rare and usually confined to the spines and laminae in the thoracic or cervical region, or at least to the posterior portions of the vertebrae. The injury to the cord is less severe and less common as a rule in this class of cases, for much displacement is rare.

**Fractures from indirect violence** are *usually due to a forcible bending of the spine in a fall or by the weight of a falling body*. The breaking of the neck by diving in shallow water is an example. The *relative frequency* of the injury *in the lower cervical spine and at the thoracico-lumbar junction* may be partly explained by the free mobility at these points, by the fact that at these points a flexible and a rigid portion of the spine meet and, in the cervical region, by the small size of the bodies. Both regions where fractures are of common occurrence are far enough from the ends of the spine to be affected by powerful leverage from both sides. The sternum and ribs may also act to some extent as a splint to protect the thoracic part of the spine. As the fractures are due to forced flexion the anterior portions of the bodies may be more or less crushed, while the neural arches are pulled apart. It is noticeable that the large cancellous bodies are well adapted to resist compression while the neural arches and their connecting ligaments are well suited to resist traction. *The various processes may also be fractured*, in the cervical region in 50 per cent., in the thoracic region in 12.5 per cent., and in the lumbar region in 14 per cent. The following is the order of relative frequency for the various regions and processes; the spines in the thoracic, cervical and lumbar regions; the transverse processes in the cervical, lumbar and thoracic regions; the articular processes in the cervical, thoracic and lumbar regions. Fracture of the articular processes increases the liability of displacement by removing one of the posterior processes which tend to lock the vertebrae together.

In the cervical and thoracic regions, particularly, *the displaced parts may often be returned to the normal position*. This may occur *spontaneously*, so that on examination no irregularity of contour is discovered, or it may be done *by the surgeon*, more readily after dislocation than after fracture. **The line of fracture** is usually nearer the upper than the lower surface of the bodies and there is more or less laceration of the contiguous disc in all cases, as well as of the ligaments connecting the spines, laminae and articular processes. The injury to the bones is the least important part of fracture dislocations of the spine, that of the contained cord is the most so. The latter from its size, which is smaller than that of the canal, and from its method of suspension in the vertebral canal (see p. 492) may escape injury, and is injured only when the lumen is considerably encroached upon by the displacement of the fragments. This **displacement** is almost always *of the upper fragment forward*, or perhaps forward and downward, on the

lower. The *cord* is thus compressed against the sharp posterior edge of the vertebral body below the line of fracture. Thus the anterior or motor portion of the cord suffers first and foremost and, if the crushing of the cord is not complete, sensation, which is conducted in the posterior part, may be retained in whole or in part. The reflexes centering in the central gray matter may also be preserved.

The symptoms are largely those of the injury to the cord. In fractures in which there is or has been no displacement there may be almost no symptoms, except those resembling a severe sprain, or perhaps those due to hemorrhage. The external deformity shows only a displacement of the vertebrae or a lesion of the laminae and spinous processes. This external deformity consists in an antero-posterior or lateral deviation of the spines at the point of injury.

The spinal canal is opened by laminectomy in certain cases of fracture dislocation of the spine, especially when the symptoms do not indicate a complete crushing of the cord or when the lesion is below the level of the cord in the region of the cauda equina, as well as in some cases of pressure paralysis with beginning degeneration in Pott's disease, and in cases of tumors within the canal. The cord is then relieved of pressure by the removal of its cause. In this operation the spines and laminae are removed, the latter as near as possible to the transverse processes. The spines and laminae are exposed by a free median incision and by the detachment and retraction to either side of the overlying muscles. Plexuses of veins on the outer and inner surfaces of the laminae and along the spines may give rise to considerable venous bleeding.

### The Spinal Cord.

**Topography.**—The spinal cord extends to the end of the spinal canal in early foetal life, to the third lumbar vertebra at birth and to the lower end of the first lumbar vertebra in the adult. It is raised 1 cm. when the body is bent forward and the arms are raised. The spinal membranes, containing cerebrospinal fluid, reach to the level of the third sacral spine, so that injuries here may produce spinal meningitis. The cervical enlargement is opposite the fifth and sixth cervical vertebrae and measures 13 mm. transversely, the lumbar enlargement is largely opposite the twelfth thoracic vertebra and measures 12 mm. transversely. In the thoracic region the cord measures 10 mm. transversely and 8 mm. antero-posteriorly. It averages 1½ feet in length and 1½ ounces in weight.

The manner in which the cord is suspended within the vertebral canal, which it does not nearly fill, accounts in part for its frequent escape from injury. The strong spinal dura forms a tubular sheath (*theca*) for the cord and an investment for each nerve as it passes through it. It is continuous with the dura of the cranium but, unlike it, does not serve as the periosteum of the bones bounding the canal, but is separated from them by a considerable interval containing loose areolar and fatty tissue and plexuses of veins. The latter may give rise to extensive hemorrhage in injuries to the spine, and the

extravasated blood *tends to gravitate* toward the lower level of the canal, where sufficient quantity may collect to cause pressure symptoms. So tough and loosely connected with the bones is the dura that it is usually un torn, even when the cord is completely crushed by a fracture. Inflammation of the dura and also of the underlying meninges, after injuries of the spine, is much less frequent than similar complications after injuries of the skull. By the communication through the ligamenta subflava between the dorsal spinal veins, on the posterior aspect of the neural arches, and the venous plexuses within the canal inflammation may travel from without to the spinal meninges. In this way spinal meningitis has followed carbuncle at the back of the neck or deep bed-sores over the sacrum.

The subdural space, or the space between the dura and arachnoid, in the spinal canal is merely a potential one, the two membranes being normally in contact. The subarachnoid space, however, contains a large amount of cerebrospinal fluid which surrounds the cord. The cord is suspended in this fluid, being connected with the layers of the meninges just mentioned only by the nerve roots and the ligamentum denticulatum on either side, and the septum posterius behind. These processes serve to steady the cord, surrounded by fluid, in its position within its theca.

*This fluid is continuous with the subarachnoid fluid about the brain and, through the foramen of Magendie, with that within the cerebral ventricles.* Thus in the case of a spina bifida, which contains this same fluid, fluctuation may sometimes be felt at the anterior fontanelle on compressing the tumor, and when the fluid is drained from a spina bifida so much may escape that the brain loses the support of its water bed and convulsions may occur from its irritation. Convulsions may also occur in lumbar puncture if the pressure is too much reduced. The normal pressure of this fluid in the recumbent position is said to support a column of water two inches high, but in inflammation and some other diseased conditions it may reach many times that amount. Normally the fluid is absorbed when its pressure is greater than that in the surrounding veins, and in diseased conditions the pressure may be relieved by lumbar puncture. In spinal cocainization as much fluid is withdrawn as solution is to be introduced, so as not to alter the pressure. The percentage of albumin in this fluid is very low, .05 per cent., far below that of blood serum, but it is greatly increased in inflammation and thus is a diagnostic sign. Lumbar puncture is also useful diagnostically by allowing a bacteriological and microscopic examination of the fluid, and, as this fluid comes from about the brain as well as the cord, it is useful in some cerebral conditions. Thus tubercle bacilli are often found in cases of tubercular meningitis and the diplococci of cerebrospinal meningitis in cases of the latter. The presence of numerous cells indicates inflammation and that of blood a pachymeningitis or an injury. Therapeutically it has proved of little value. It suggests itself in hydrocephalus, but is nothing more than palliative. In a few cases of spinal injury it appears to have been

PLATE LIX.

FIG. 123.

Section of the cord and its membranes to show the manner of suspension of the cord within the vertebral canal. Diagrammatic. (Testut.)

serviceable. By means of the free communication established by this fluid between the spinal and cranial cavities it affords a ready means of the spread of inflammation from one to the other. Blood extravasated into the subdural or subarachnoid spaces, in case of injury, may readily extend from end to end of the cord and tends to gravitate toward its lower end, but extensive hemorrhage in these spaces is not common.

In spite of the marvelous provision for protection of the cord a train of severe and complicated symptoms sometimes follows certain injuries to the spine. These symptoms are attributed by some to **concussion of the cord**, comparable to concussion of the brain, but they are more complex than the symptoms of the latter. The explanation of these symptoms as due to certain molecular changes in the cord is disputed by most surgeons, partly on the anatomical ground that the provisions for the protection of the cord would not admit of such a lesion. Such symptoms *probably depend upon a distinct lesion* of the cord, such as hemorrhage (*haematomyelia*), the diagnosis of which, says Thorburn, when the symptoms may be attributed to a single focus of injury, "should always be preferred to the vague and unsatisfactory designation 'concussion of the spinal cord.'" Many supposed cases of the latter will probably be eliminated by accurate study. The *lesion is probably due to a partial dislocation with recoil, an acute bend, or a diastasis (separation) of the spine.*

**Compression, contusion or crushing of the cord** is what *constitutes the gravity of fracture-dislocations* of the spine. Compression may also be due to tumors, inflammatory deposits, etc. As stated above, in fracture-dislocations with displacement the cord is compressed or crushed by being pressed by the neural arch above the line of fracture against the sharp postero-superior edge of the body below the fracture line. The anterior part of the cord is therefore first and, when the entire cord is not crushed, most affected by the injury.

It is important therefore both for diagnosis and prognosis to know something of the **conduction paths of the cord**. *The direct pyramidal tract*, or column of Türk, in the mesial part of the ventral column, conveys motor fibers from the cortex on the same side, which have not crossed in the pyramids. They eventually reach the opposite side by passing through the anterior white commissure. *The crossed pyramidal tracts* lie in the postero-mesial part of the lateral columns and convey motor fibers which have crossed in the pyramid from the cortex of the opposite side. Lesions of these two columns cause a paralysis of the muscles below. The muscles are not atrophied unless the anterior cornu of gray matter is involved. *The direct cerebellar tract* on the postero-lateral aspect of the lateral column, separating the crossed pyramidal tract from the periphery, and the *dorso-lateral*, or Burdach's column, are *ascending or sensory tracts* carrying sensory impressions upward. They and the sensory or posterior horn of the gray matter are situated on the dorsal aspect of the cord. The column of Burdach also contains *fibers that coördinate muscular movements* so that in lesions

of this part there is ataxia in addition to peripheral pains and impaired sensation. In the antero-lateral column are the *fibers which inhibit the reflexes* and thus keep them under control of the brain. When the lesion involves these fibers the inhibitory control of the brain is lost, the reflexes are exaggerated and a spastic contraction results, which, in connection with the motor paralysis, is called spastic paraplegia. Subsequently the muscles become contractured. If the *reflex centers* are destroyed the reflexes are lost. These centers are in the gray matter.

The distinction between total and partial transverse lesions is important. *In partial transverse lesions*, when paralysis and anaesthesia are complete but the deep reflexes are exaggerated or normal, or when the anaesthesia is not complete, *operation* (laminectomy) offers some hope and is justifiable. Many condemn operation *in complete transverse lesions* on the ground that the case is hopeless, but it is not invariably so, and in many such cases great improvement or nearly complete cure has resulted. *The reparative power of the cord* is great, so that after severe crushing the function may be recovered to a greater or less extent. Recent experience in the surgery of the cord is on the whole encouraging. *The cauda equina* and the nerve roots are *practically peripheral nerves* and hence resist trauma well, so that operation should be the rule in injuries of the cauda equina, especially if after six to ten weeks the bladder and rectum symptoms persist.

**The determination of the level of the lesion** is important not only in traumatic lesions, but even more so in those due to a tumor or an inflammatory deposit. For this purpose there are *three means at our disposal*: the extent (1) of the sensory paralysis and (2) of the motor paralysis, and (3) the condition of the reflexes of each segment. From these we can judge what nerves and therefore what spinal segments are involved. *The cord is divided into as many segments as there are spinal nerves.* *Each segment includes* the roots of a pair of spinal nerves, the dividing line between two adjoining segments passing transversely between the superficial origins of the pairs of nerve roots. Remember that the cervical nerves appear above their respective vertebrae, the thoracic and lumbar nerves below.

It is most important to remember that *the level of the segment*, or the superficial origin of the nerve from the cord, is *higher than the exit of the nerve* through an intervertebral foramen. In other words the nerve roots run without the spinal canal and alongside of the cord for a distance which varies with different nerves and is greater in the lower part of the cord. These *nerve roots resist injury* far better than the soft cord, so that as a rule the nerve roots which, given off above, pass the site of the cord lesion are seriously involved only in the most severe injuries. It follows that, the site of the fracture being known, when the anaesthesia extends to this level the lesion is so severe as to crush the nerve roots as well as the cord and the prognosis is correspondingly bad. *As a rule, we must expect the level of the paralysis and anaesthesia to be lower than the vertebral lesion by the length of the intraspinal course of the nerve roots at that point.* The nerves whose

roots pass the lesion may perhaps show some paræsthesia, hyperæsthesia or pain, but the pain like the anaesthesia is almost always referred to a lower level than the lesion, on account of the intraspinal course of the nerve roots. Horsley says it is necessary to very accurately determine the upper border of the hyperæsthetic and paræsthetic zones, above the anaesthetic zone, and the cord should be explored to the highest level suggested by any definite symptoms, including even slight paræsthesia. This is especially important as it is the experience of many operators to have found the lesion higher than it had been placed by the neurologist.

The following table gives the *points of origin of the nerve roots* from the cord with reference (1) to the bodies and (2) to the spines of the vertebrae opposite them :

First cervical nerve .....	Interval between atlas and occiput	Between the occiput and the sixth C. spine. These spines, except the latter, cannot be felt.
Second and third cervical nerves.....opposite the axis.....		
Fourth to eighth     "     "(incl.) op. third to seventh C. vertebrae respectively.		
First thoracic nerve .....	op. disc below seventh C. vertebra.....	Seventh C. spine.
Second     "     " .....	op. disc below first T. vertebra.	
Third     "     " .....	op. disc below second T. vertebra.....	First T. spine.
Fourth     "     " .....	op. disc below third T. vertebra .....	Second T. spine.
Fifth and sixth thoracic nerves.....op. lower border of fourth and fifth T. vertebrae respectively .....		Third and fourth T. spines respectively.
Seventh to twelfth     "     "(incl.) op. lower border of sixth to eleventh T. vertebrae respectively .....		Fifth to tenth T. spines respectively.
First to third lumbar nerves.....op. twelfth thoracic vertebral.....		Opposite eleventh and twelfth T. spines.
Fourth     "     nerve.....op. disc below twelfth T. vertebra.....		
Fifth     "     " .....	op. upper border first L. vertebra .....	
First to fifth sacral nerves (incl.).....op. first L. vertebra.....		First L. spine.

The *areas of anaesthesia* corresponding to the several segments of the cord are seen by reference to Fig. 124. It will be seen that only when the first lumbar segment is involved does the anaesthesia extend up to the abdominal wall. By the area of anaesthesia alone it is impossible to definitely determine lesions of the cauda equina from those of the segments from which they are derived. In all cases the localization of the injury of the cord must be made from the symptoms observed shortly after the injury for within a few days myelitis is apt to occur and cause an extension of the area of anaesthesia and paralysis.

For the interpretation of the muscular paralysis three methods of determining the localization of the segments which correspond to the nerve supply of the muscles have been employed : (1) the experimental, on monkeys, (2) the clinical from an accurate observation of cases, and

(3) the anatomical from minute dissections. Although perhaps less accurate than the others *the clinical method* is still of the most practical service and hence column D of Fig. 125 gives the results obtained by Thorburn from an analysis of careful clinical observations.

FIG. 124.

Cutaneous sensory distribution of the spinal segments on the anterior and posterior surfaces, from the third cervical to the fourth sacral, inclusive. (After KOCHER.)

According to Thorburn no motor supply comes from the first and second lumbar segments but many derive part or the whole of the nerve to the cremaster from them. It will be seen that *motor paralysis is slight in the lower cord lesions*, only the perineal muscles, bladder and rectum being involved in lesion just below the second sacral segment and, with the possible exception of the glutei, only the leg and foot muscles are affected if the lesion involves all the sacral segments. In pressure lesions of the cauda equina the pressure may be sufficient to cause widespread paralysis when sensation is but slightly affected. Also

FIG. 125.

Topography and distribution of the spinal nerve-roots. The brackets in column A show the extreme limits between which in different subjects examined by Reid each group of nerve-roots was found to arise. Column B shows each nerve cut off at the level of its intervertebral foramen, thus showing the obliquity of its course in the neural canal. Column C gives the vertical distance in millimeters which, in Testut's case of a subject 18 years of age, separated the superficial origin of each of the nerves marked from its intervertebral foramen.

in such lesions the nerves which pass out lower down are more seriously involved though they are situated nearer the center and would appear to be less exposed to pressure, a fact that is not explained.

According to Starr *the control of the bladder and rectum* is always *lost together*. It is lost if the lower three sacral segments are involved, and the control centers probably lie in the lower two of these. *In a lesion involving these reflex centers* absolute incontinence follows temporary retention, the bladder first distends and then dribbles from over-distension. *In a lesion above these centers* the cerebral inhibitory control is cut off so that, after a temporary retention due to shock, the bladder and rectum are emptied at frequent intervals unconsciously and involuntarily. The reflex mechanism being intact works like a clock without a pendulum. Similarly in lesions above the *reflex center of erection of the penis*, which is in the same part of the lumbar enlargement, the inhibitory fibers are cut off and a chronic erection (*priapism*) usually occurs.

Thorburn has called attention to *the pathognomonic posture assumed in lesions below the fifth cervical segment* and the explanation of it. The arms are abducted by the deltoid, and rotated out by the supra- and infra-spinati, the elbows are flexed by the brachialis, brachio-radialis and biceps and the hand is supinated by the latter, all the other muscles of the arm being paralyzed. As *the phrenic nerve* is derived principally from the fourth cervical segment, receiving contributions from the third and fifth segments, lesions at or above this level are rapidly fatal from failure of respiration. In lesions between this and the upper thoracic segments the respiration is entirely diaphragmatic.

*The integrity of the spinal reflexes depends upon that of the afferent sensory nerve, the efferent motor nerve, their connection in the gray matter of the cord, and the inhibitory fibers, descending in the antero-lateral columns, by which the brain regulates the reflexes.* If the latter fibers are destroyed by a lesion all reflexes below this point are exaggerated from the loss of cerebral control. If the afferent or efferent nerves or their association in the gray matter is destroyed the reflex is lost. *The reflexes, with the segments to which they correspond clinically, are given in column F of Fig. 125.*

**Hemorrhage** may occur within the cord (*haematomyelia*) or within the membrane's (*haemorrhachis*). The latter may extend the length of the cord or gravitate largely to the lower end, and produces no very localized symptoms. According to Thorburn, *haematomyelia* is not at all uncommon and *occurs principally* between the fourth cervical and the first thoracic segments (inclusive), corresponding to the cervical vertebrae from the fourth to the seventh inclusive. This is the summit of the cervical curve, where an acute bend of the neck would make itself mainly felt. In fact the cord has been crushed by such a bend without fracture, and with only temporary diastasis. *The symptoms produced by such a hemorrhage depend upon* (1) a compressing and (2) a destroying lesion; the former temporary and causing paralysis, anæ-

thesia, loss of control of the reflexes of the bladder, rectum and penis, etc., the latter permanent and causing atrophic paralysis, and perhaps anaesthesia, of the parts supplied by some of the roots of the brachial plexus. *These hemorrhages are most severe in the center of the cord* so that the more peripheral fibers, which emerge near the lesion, may not be affected by the eccentric pressure, while the more central fibers, which emerge lower down, are more and more affected; hence the area of anaesthesia is ill defined and may be far below the seat of the lesion. Some doubt is thrown on the correctness of this explanation by the fact, stated by Horsley, that the same tendency to involve the lowest sensory fibers first is found in the case of tumors, whose pressure is concentric. *In tumors the invasion of paralysis is from above downward, or the reverse of that of anaesthesia.* The favorite situation for tumors is below the middle of the cervical region and at the upper and lower ends of the thoracic region.

**Operations upon the cord**, in addition to those for fracture-dislocations, are not infrequently done for tumors, or inflammatory deposits, the operator being guided by the above and other minor points of localization. The cord is first exposed by a laminectomy. Such operations have been very successful when the tumor has been removed and the operation was not too long deferred.
